

Sparse Production Networks*

Andrew B. Bernard[†] Yuan Zi[‡]

September 2022

Abstract

Firm-to-firm connections in domestic and international production networks play a fundamental role in economic outcomes. Firm heterogeneity and the sparse nature of firm-to-firm connections implicitly discipline network structure. We find that a large group of well-established statistical relationships are not useful in improving our understanding of production networks. We propose an “elementary” model for production networks based on random matching and firm heterogeneity and characterize the families of statistics and data generating processes that may raise underidentification concerns in more complex models. The elementary model is a useful benchmark in developing “instructive” statistics and informing model construction and selection.

JEL Classification: F11, F14

Keywords: firm-to-firm networks, model selection, balls-and-bins, buyer-seller matching, underidentification

1 Introduction

From the propagation of microeconomic shocks into the aggregate economy to the determinants of international trade flows to the sources of heterogeneity in firm size and performance, firm-to-firm connections in production networks are increasingly viewed as playing a fundamental role in shaping economic outcomes. Recent research has taken advantage of the proliferation of data on international trade transactions and firm-to-firm connections in domestic production networks to establish a set of common empirical regularities on buyer-seller relationships and the evolution of the production network. These regularities, or stylized facts, have in turn disciplined approaches to modeling and testing the nature of firm-to-firm connections and their consequences.

Production networks are fundamentally sparse. Firms make finite and discrete transactions, but, even for narrowly-defined products, there are large numbers of buyers and sellers, meaning most buyer-seller pairs are not linked. This fundamental sparsity, coupled with firm heterogeneity, implicitly disciplines the structure of production network. This paper shows that most of the established stylized facts on firm-to-firm networks are, in fact, not informative for developing associated models on how buyer-seller relationships are established, nor for guiding related empirical tests. Conditional on buyer and seller heterogeneity, a simple allocation model with purchases from buyers randomly assigned to sellers based solely on buyer and seller size is equally capable of generating a sparse production network and the additional empirical facts used to motivate, and often verify, more complex models of firm-to-firm connections.

This simple allocation model of production networks, henceforth the “elementary” model, generates a rich set of statistical relationships that match those from numerous existing datasets. A key point is that as the data becomes more disaggregated, the more sparse, granular, and stochastic it becomes. A discrete, stochastic model thus provides a more realistic characterization of data than a continuous, deterministic model. Continuity itself has implications for network structures, necessitating the introduction of additional mechanisms to explain certain network features. Forgoing continuity, generally assumed for modeling simplicity, firm heterogeneity can result in rich network structures that match the data well.

In addition to matching existing stylized facts and empirical results, we develop the general properties of the elementary model, characterizing the *families* of statistics it gen-

erates. Rather than having to take every empirical prediction of a model to the data, the researcher can easily pin down the corresponding prediction of the elementary model for *any* empirical fact in a given family. This paper focuses on three issues confronting researchers deciding how to present empirical characteristics of their data: (1) What statistical transformation should be applied? (2) What level of aggregation should be considered? (3) What variables of interest should be examined and how should they be linked? Choices in these three areas collectively determine how a researcher presents empirical findings.

We present the connection of the elementary model to three general classes of statistical transformations: monotonic statistics such as intensive and extensive margins, order statistics such as percentiles, and higher-order relationship statistics such as assortativity. Then, we show that all results from the elementary model that hold at a disaggregated level are maintained with aggregation. Finally, if two variables of interest, such as productivity and size, are first-order stochastically monotone in the realization of any variable that the model directly generates, e.g., pairwise flows between buyers and sellers, their correlation can be pinned down. These findings suggest that, on the one hand, the elementary model provides a natural benchmark for characterizing real-world production networks due to its simple yet rich properties; on the other hand, a large group of statistics may not be informative in providing insights on firm-to-firm relationships beyond random matching.

Our findings suggest that the elementary model is a powerful tool to select informative statistics and benchmark theories. Researchers can use the elementary model to discern statistics that are “instructive” for the development of more elaborate models of production networks. “Instructive” statistics can take two broad forms. First, those statistics which cannot be produced by the elementary model because they have a different sign than that predicted by the elementary model. Second, related to a suggestion by Armenter and Koren (2014), while the signs of some statistical relationships may not be informative, the magnitudes may be if they differ substantially from the predictions of the elementary model. We use Norwegian transaction level trade data to illustrate both ideas with examples.

In addition, we propose to use the elementary model as a benchmark to select theories. This is a slightly different thought experiment: instead of starting from data and the elementary model with minimum structure, we start from a candidate model and compare its explanatory power to the elementary model. For example, the matching probability between buyers and sellers (ρ_{ij}) across different buyer-seller bins in the data is close to

what is predicted by the elementary model. In contrast, models emphasizing assortativity in matching perform much worse in every buyer-seller bin. This poor performance may appear puzzling at first glance as these models are developed to understand firm-to-firm networks. However, while models as such are intended to explain how buyers match sellers – the data counterpart is the *distribution* of ρ_{ij} – what they actually match are *certain statistics* of ρ_{ij} , such as the sign of assortativity. To match these statistics, strong assumptions are often imposed, which generate greater prediction errors in untargeted statistics and ultimately in the distribution of ρ_{ij} .

Finally, in the last part of the paper, we approach theory comparison from a more structural perspective and introduce the idea of Bayesian model selection. We show that Bayes’ theorem gives a natural characterization of how we move from empirical evidence to theory. It enables us to think about preferences for a certain theory as a product of its ability to explain the data and prior beliefs compared to alternatives. We show that the elementary model is so far the best baseline alternative, for selecting richer structural models of production networks.

The primary concern about random-allocation models is that they are statistical models lacking economics. However, we show that if the allocation is designed with the correct economic counterpart, it can be viewed as an intermediate step of a discrete choice model. The elementary model can be derived from a competitive environment, with Eaton and Kortum (2002, henceforth, EK) being a special case.¹ This view further suggests that when linking a model to data, the allocation problem needs to be designed with the correct data counterparts. Otherwise, implicitly, we are imposing additional assumptions (often inconsistent with empirical context or the model itself) on the distribution of firm-to-firm sales. We use the firm-level balls-and-bins models designed by Bernard et al. (2018a) and Armenter and Koren (2014) as examples to illustrate this point. These balls and bins models fail to match relevant moments in the data either because the balls-and-bins counterpart is misspecified or because of additional assumptions made in the simulations.

The elementary model can also be used to understand network adjustments to shocks. We show a rich set of partner switching patterns between Mexican exporters and US im-

¹The model of Ellison and Glaeser (1997), where the geographic concentration of an industry is an outcome of a sequence of profit-maximizing location decisions made by individual plants, is one example of the general model presented Section 5.2. In Ellison and Glaeser (1997), idiosyncratic location preferences are assumed to follow Weibull distribution, which is one example of an distribution that follows the *FSD* ordering.

porters in response to the end of the Multifiber Arrangement (MFA) documented in Sugita et al. (forthcoming) can be explained by the elementary model. In other words, the changes in the existing network in response to shocks may not be sufficient to identify specific, more complex matching mechanisms between buyers and sellers. As transactions represent the foundation of any aggregate relationship, the findings also raise concerns regarding whether existing empirical regularities at more aggregate levels can distinguish between competing economic models. We illustrate this point by focusing on firms, showing that heterogeneous responses of firms to improved market access or exchange rate changes in Berman et al. (2012) can be generated by heterogeneous firms randomly reshuffling buyer-seller links in response to increased foreign demand rather than pricing-to-market adjustments.²

Thus far, we have emphasized the importance and potential benefits of our findings. It should be clear that our work also has important limitations. The approach is not useful in uncovering the microfoundations of firm heterogeneity. In most of the paper, we implicitly treat buyer and seller heterogeneity as model primitives, the identification of which would require additional data and research design. Therefore, our work should be viewed as complementary to studies that examine the sources of firm heterogeneity (e.g., Atkin et al., 2017; Cai and Szeidl, 2018; Bernard et al., 2022; Alfaro-Urena et al., 2022; Miyauchi, 2021).

The elementary model is a balls-and-bins model which is part of a set of classic problems in probability theory with wide applications in statistics and computer science.³ Our paper is related to Armenter and Koren (2014), who first brought the balls-and-bins to international trade, and explained why the categorical nature of trade data may provide challenges in distinguishing sample zeros from fundamental zeros. In production networks there is a fundamental sparsity: buyers do not purchase from every seller of a given product. This fundamental sparsity, coupled with firm heterogeneity, implicitly disciplines the structure of production network. We augment Armenter and Koren (2014) and consider a general version of the allocation problem, in which the number of transactions differs across buyers, and buyers and sellers are allowed to overlap. We characterize the model's statistical features under general classes of statistical transformations, where the extensive margin is one special case. It is important to note that the goal of this paper is not to

²As Berman et al. (2012) correctly note, their findings are consistent with any models where the demand elasticity decreases with firm performance.

³See Mitzenmacher and Upfal (2017) and Raab and Steger (1998) for a brief overview. Additionally, Roch (2015) provides an excellent reference for the modern treatment of discrete probability.

propose any particular model or to explain any particular set of facts. Rather, we focus on the basic structures required for a model to adequately explain empirical findings on production networks, acknowledging the discreteness and sparseness nature of firm data at a very disaggregated level.⁴

Our work contributes to the growing literature on domestic and international production networks. Beginning with Blum et al. (2010, 2012) (Chile and Colombia), researchers have made use of the increasing number of datasets with information about the identities of both buyers and sellers.⁵ These papers document stylized facts about the firm-to-firm networks, develop theoretical models and test their predictions. Chaney (2014) models the current and future export destinations of French firms; Bernard et al. (2018a) examine the role of buyer and seller heterogeneity and firm-level adjustments to trade shocks; Bernard et al. (2022) consider the role of the network in firm size heterogeneity; and Sugita et al. (forthcoming) examine the removal of the Multi-Fiber Arrangement on Mexican textile exports to the US. We offer a benchmark model of firm-to-firm connections based on random matching and firm heterogeneity, emphasizing the sufficient model structure in matching rich existing stylized facts and comparative statics.

In terms of spirit, the emphasis of the paper on sufficient model structure in explaining rich empirical facts is related to Chaney (2018), who provides sufficient conditions for trade being inversely proportional to distance, and to Costinot (2009), who offers a unifying perspective on the fundamental forces that shape comparative advantage. Our work is also related to a large literature on model selection. Even though model-selection methods have become increasingly important in other scientific disciplines (Hooten and Hobbs, 2015; Madigan and Raftery, 1994), they are not commonplace in research on international trade or production networks. We show the problem of model selection generally exists in empirical production network studies, and we propose to use the elementary model to select theory

⁴In a recent paper, Herkenhoff et al. (2021) explain a similar set of existing stylized facts on exporters and importers in international trade by re-interpreting the Krugman (1980) model with randomly bundled varieties and statistical reporting thresholds for cross-border transactions. Their approach follows much of the literature by starting with a continuum of heterogeneous firms and adding constraints to match the sparse nature of the data. Sheveleva (2022) presents a statistical model with random product size focusing on explaining the intensive profitability of multi-product exporters.

⁵See among others Atalay et al. (2011) (US), Bernard et al. (2018b) (Colombia), Kramarz et al. (2020) (France), Carballo et al. (2018) (Costa Rica, Uruguay and Ecuador), and Lim (2020) (US). Bernard and Moxnes (2018) survey the recent literature. Relatedly, there is a large literature on the macroeconomic consequences of the microstructure of production networks. Some papers utilize micro-level firm-to-firm data (e.g., Lim (2020), Carvalho et al. (2021)), while others do not (e.g., Baqaee and Farhi (2019)). Carvalho and Tahbaz-Salehi (2019) provides a review of the literature.

and benchmark empirical results.

In terms of results, our paper is related to research on how random allocation may lead to seemingly nonrandom outcomes. Ellison and Glaeser (1997) study whether the observed levels of geographic concentration of industries are greater than would be expected to arise randomly. Dingel and Tintelnot (2020) note that granularity could lead to confusion between sample zeros and fundamental zeros in spatial studies. Borusyak and Hull (2021) show how random shocks may lead to nonrandom exposure and bias estimation results. While the above-mentioned papers focus on geography, our interest is in production networks. In terms of technicalities, the paper introduces coupling methods to the production network literature and demonstrates that they are powerful tools for stochastic comparative statics analysis and in characterizing real-world firm networks.

The difficulty in describing production networks lies in their complex structure. In this paper we show the topology of production networks is primarily governed by simple yet robust organizing principles. In this regard, our paper contributes to the large literature on statistical mechanics of complex networks.⁶ The networks studied in this literature (e.g., world wide web, social network, nervous system) exhibit very distinct topological and dynamic features, and hence are explained by different network formation principles (Barabási and Albert, 1999; Bollobás et al., 2001; Albert and Barabási, 2000).⁷ Moreover, none of these papers provides analytical results on comparative statics.

Overall, the contribution of this paper is threefold. First, we show that many well-established statistical relationships may not help in improving our understanding of production networks. Second, we propose an elementary model to characterize the organizational principles of production networks and describe the general statistical families that may subject a more elaborate model to underidentification concerns. Finally, we demonstrate that the model is a useful benchmark for selecting informative statistics and for model comparison. As micro-level data from firms becomes increasingly available, the number of relationships or variable combinations that can be examined will rapidly grow. Our work will serve as a useful guide for connecting data to theory.

⁶See for example Barabási and Albert (1999); Albert and Barabási (2002).

⁷One distinct feature of networks studied in these papers is positive degree assortativity (instead of the negative degree assortativity found in production networks). This among other things is explained by the growth and the preferential attachment principles. Generally speaking, these papers are more interested in the development (expansion) of networks. In spirit, they are closer to Chaney (2014), which studies the dynamic formation of an international network of exporters. A more detailed discussion of this model feature can be found in Chaney (2016).

The rest of the paper is organized as follows. Section 2 presents a set of existing stylized facts on production and trade networks. Section 3 develops the elementary model and the theoretical counterparts of the stylized facts. Section 4 studies the general properties of the model. Section 5 derives the model from a competitive environment. Section 6 demonstrates that the model also matches a rich set of data responses to shocks. Section 7 shows that the elementary model is a useful benchmark in developing “instructive” statistics and informing model construction and selection. Section 8 concludes.

2 Stylized Facts on Production Networks

We first briefly review the existing empirical literature on firm-to-firm production networks, both international and domestic. We highlight a set of facts common to empirical work on a variety of countries. These facts have been the basis for many of the models of firm-level production networks.

Fact 1. *Production networks, both domestic and international, are sparse.*

In every production network examined to date, most buyers and sellers are not connected. In Japan (Bernard et al., 2019), fewer than 1 in 130,000 potential buyer-seller connections are active in the domestic production network, while in Belgium, the figure is 1 in 23,000 (Dhyne et al., 2015).

Even conditioning on firm participation in a particular international market, buyer-seller connections are sparse. For Colombia, Bernard et al. (2018b) find that fewer than 1 in 15,000 connections exist between Colombian firms that import and foreign firms that export to Colombia. Comparable numbers are 1 in 12500 for French exporters and importers from France and 1 in 9000 for Norwegian exporters and firms that import from Norway (Kramarz et al. 2020 and Bernard et al. 2018a).

Fact 2. *Firms in a production network are heterogeneous in the number of links and the value per link.*

Both the out-degree (number of buyers per seller) and in-degree (sellers per buyer) show substantial dispersion across firms. The most connected exporters (90th percentile) have 6.5 to 11 times as many foreign customers as the median exporter in Costa Rica, Uruguay and Ecuador (Carballo et al., 2018). Similar dispersion of connectivity is found in Norwegian

exporters (Bernard et al., 2018a), Colombian importers (Bernard et al., 2018b) and in US, Japanese and Belgian domestic production networks (Atalay et al., 2011; Bernard and Moxnes, 2018; Bernard et al., 2022).

The value of trade between pairs of firms is also highly skewed. For the Belgian domestic network (Dhyne et al., 2015) and for Costa Rican, Ecuadorian and Uruguayan exporters (Carballo et al., 2018), the ratio of the sales of the 90th percentile pair to the 50th percentile pair is greater than 12.

Fact 3. *The largest firms in terms of sales have the most buyers and suppliers and reach the largest number of markets (cities or countries).*

The largest firms in terms of sales account for a large majority of economic activity in the production network. They have the greatest number of buyers and suppliers and connect to the most (domestic and foreign) markets, e.g. Japan (Bernard and Moxnes, 2018), Norway (Bernard et al., 2018a), Chile (Blum et al., 2012), and Belgium (Dhyne et al., 2015).

Fact 4. *Negative degree assortativity: Firms with many connections, on average, trade with firms that are less well connected.*

Production networks typically exhibit significant negative degree assortativity: highly connected firms sell to more customers, but their average customer purchases from a relatively small number of suppliers. The same is true on the purchasing side, highly connected buyers, on average, buy from less-connected sellers. This relationship has also been confirmed using production-network data from various countries, time periods, and for both within- and cross-country networks (e.g., Lim 2020 for US Compustat data; Bernard et al. 2019 for Japan; Bernard et al. 2022 for Belgium; Bernard et al. 2018b for Colombia).

Fact 5. *Hierarchy: Well-connected firms trade with a range of partners from the best-connected to the least. Firms with few connections match with well-connected partners.*

Notably, negative degree assortativity does not mean that well-connected sellers only sell to poorly connected buyers. The best connected (most productive) firms sell to a wide range of buyers, from the best connected (most productive) down to the least connected (least productive). Less connected (low-productivity) sellers, however, only connect to high-productivity partners. The hierarchical nature of production networks is presented

explicitly in Bernard et al. (2019) and Blum et al. (2012), but it is a common feature shared by many datasets and has been implicitly or explicitly incorporated in most of the related production network models.

While these facts do not cover the entirety of the empirical work on firm-to-firm production networks, they are often used to motivate theoretical models of buyer-seller, or importer-exporter, interactions. In particular, sparseness of connections in production networks has important implications for the modeling of firm-to-firm connections. Models with continuity generally require fixed costs to prevent all (or most) firms from buying or selling to one another. Assortativity on the other hand motivates various matching and sorting mechanisms. In such instances, only the best sellers find it profitable to incur fixed costs and reach small buyers (e.g. Bernard et al., 2018a; Bernard and Moxnes, 2018; Lim, 2020; Sugita et al., forthcoming).

In the next section, we ask whether these empirical regularities on buyer-seller matches are informative and show that a simple discrete model of buyer-seller transactions based on random matching and firm heterogeneity can match these facts.

3 A Random Allocation Model

We model the assignment of transactions from buyers to sellers as balls falling into bins. By doing so, we capture the discrete nature inherent in the micro-level data, as a firm’s revenue consists of a finite number of orders placed by its customers, each of which is a discrete unit of observation and is the micro-foundation of more aggregate statistics at the level of the firm, buyer-seller, country, or origin-destination.

3.1 Basic Environment

Consider an economy with $M \geq N$ buyers, indexed by subscript $j \in \{1, 2, \dots, M\}$. Each buyer makes $b_j \geq 0$ purchases and buyers are ordered such that $b_j \geq b_{j+1}$. By one purchase we mean one-unit of a product. To fix ideas, we first consider the case in which all purchases are identical in value (we relax this assumption in Appendix A.4).⁸ Similarly, let $N \geq N$ be the number of sellers, indexed by subscript $i \in \{1, 2, \dots, N\}$. The probability that any

⁸As shown in Appendix A.4, relaxing this assumption does not change the results presented in the paper in any meaningful way. A sufficient assumption is that a firm’s total sales are positively related to total number of transactions, which is supported by all transaction-level data sets used to date.

purchase lands on seller i is characterized by s_i , with $s_i \in [0;1)$ and $\sum_i s_i = 1$. Sellers are ordered such that s_i is weakly increasing in i .⁹ As in equilibrium the expected size of a seller will be positively associated with s , we sometimes refer to s and b as seller size and buyer size, respectively.

The setup is simple and is based on only two natural and verifiable assumptions: (1) buyers vary in terms of their level of purchases while sellers have different abilities to attract buyers; and (2) buyer-seller matches are not deterministic. We refer to the formulation in terms of s , b and the allocation rule as the “*elementary model structure*”: any two models with the same formulation will give rise to the same network structure regardless of their micro-foundations. Correspondingly, we refer to our model as the “*elementary model*” of production networks.

We make no assumptions on how sellers and buyers overlap. A node in the network can be a buyer and a seller at the same time, with sales and purchases being characterized by s and b , respectively. If a node has $b > 0$ and $s = 0$, it represents a firm with no sales in the network¹⁰; if $b = 0$ and $s > 0$, it represents the most upstream producer; and if the realized assignment for some nodes with $s > 0$ is zero, those nodes indicate sellers who have had no network sales in a given period.

In the remainder of this section, we illustrate how the model matches the stylized facts shown in Section 2. Our main theoretical contribution on the generalized results is introduced in Section 4. As the model belongs to the family of balls-into-bins models, sometimes when it is convenient, we will use balls and bins to explain the intuition of the results.¹¹

3.2 Extensive Margin

Given the environment, the probability that buyer j matches seller i equals the probability that the seller receives at least one purchase from j :

$$p_{ij} = 1 - (1 - s_i)^{b_j} \tag{1}$$

⁹We refer to a function as “increasing” (“decreasing”) if it is strictly increasing (decreasing).

¹⁰In datasets on domestic production networks, these firms sell entirely outside the network, i.e. entirely to individual consumers or to foreign buyers.

¹¹We can view sellers as bins of different sizes, and buyers making b_j purchases as buyers holding b_j numbers of balls. None of the results depend on the assumption that buyers throw balls and sellers are bins, as will become clear in the subsequent sections.

The probability ρ_{ij} is an increasing function of both seller and buyer size: larger sellers (buyers) are more likely to match partners of a given size than small sellers (buyers). The size distribution of firms in all datasets is highly skewed, meaning that the majority of firms have few sales and purchases, s_i is close to zero and b_j is a small number. As a result, ρ_{ij} is close to zero for most of the firm-firm connections. The model therefore generates network sparseness (Fact 1).

The expected number of buyers that a seller matches is then given by the sum of ρ_{ij} over all buyers:

$$N_i^s = \sum_j \rho_{ij} = \sum_j (1 - (1 - s_i)^{b_j}): \quad (2)$$

Similarly, the expected number of sellers that a buyer matches is given by

$$N_j^b = \sum_i \rho_{ij} = \sum_i (1 - (1 - s_i)^{b_j}): \quad (3)$$

It is easy to verify that N_i^s increases in s_i and N_j^b increases in b_j . Thus, on average, larger buyers match more sellers, and larger sellers match more buyers. Intuitively, buyers who make more purchases have a greater chance of connecting with any seller; hence they are on average more likely to match with more sellers. Sellers with greater s are more likely to receive purchases from any buyer and thus are more likely to match with more buyers on average (Fact 2).

Next, let us consider $C \subseteq \mathbb{N}$ locations indexed by $c \in \{1, 2, \dots, C\}$. The probability that seller i exports to location c equals the probability that the seller matches at least one buyer in c :

$$P[D_{ic} = 1] = 1 - \prod_{j \in c} (1 - s_i)^{b_j} = 1 - (1 - s_i)^{\sum_{j \in c} b_j}; \quad (4)$$

where D_{ic} is an indicator variable that equals one if seller i sells to c . We use $j \in c$ to indicate buyer j at location c . Therefore, the expected number of locations that a seller reaches equals

$$N_i^{sc} = \sum_c (1 - (1 - s_i)^{\sum_{j \in c} b_j}); \quad (5)$$

Again, N_i^{sc} increases in s_i because each element in the sum is an increasing function of s_i . This analysis is equivalent to treating all buyers at location c as a single representative buyer with $\sum_{j \in c} b_j$ purchases, hence the same intuition follows. Similarly, one can show

that the number of locations that a buyer reaches also increases with its size. Thus the model matches Fact 3.

3.3 Intensive Margin

Since purchases are of equal size, the total purchases of buyer j from seller i is captured by the number of orders from j to i , which we denote by x_{ij} . The probability that $x_{ij} = x$ is given by

$$P[x_{ij} = x] = C_{b_j}^x s_i^x (1 - s_i)^{b_j - x}; \quad (6)$$

where $C_{b_j}^x$ denotes the combination formula. Thus, x_{ij} follows the binomial distribution $Bin(b_j; s_i)$. Let X_{ij} denote the expected purchase amount by j from i ; we then have

$$X_{ij} = b_j s_i; \quad (7)$$

Thus, the model predicts that large sellers on average sell more to a given buyer and larger buyers purchase more from a given seller. Equations (2), (3), and (7) suggest that in the elementary model, heterogeneity in the size distribution of firms naturally translates to network heterogeneity in the number of links and the value per link (Fact 2).

3.4 Degree Assortativity

Assortativity examines the extent to which a network's nodes attach to others that are similar in some way. Although the specific measure of similarity may vary, existing studies often examine assortativity in terms of a node's degree. Unlike many other types of networks, production networks exhibit significant negative degree assortativity. This data feature has often been used to motivate the modeling of relationship-specific fixed costs. For example, only the best sellers find it optimal to incur fixed costs to reach small buyers. However, negative degree assortativity naturally emerges from the elementary model.

The in-degree of a buyer is the number of sellers the buyer matches. Its expected value is given by equation (3) and increases in b_j . The average connections of sellers that a buyer matches, by the law of iterated expectations, can be written as the sum of each seller's

expected total connection times its relative probability of matching that buyer:

$$\bar{N}^s(j) = \frac{\sum_i N_i^s \rho_{ij}}{\sum_i \rho_{ij}} := \sum_i N_i^s g(i;j);$$

where $\bar{N}^s(j)$ denotes the expected average out-degree of sellers that buyer j matches, and the probability mass function $g(i;j) := \frac{\rho_{ij}}{\sum_i \rho_{ij}}$ gives the relative probability of i matching j – in other words, $g(i;j)$ characterizes the distribution of sellers conditional on matching buyer j . Intuitively, if a buyer makes one random purchase, she has a greater probability of matching with bigger sellers; but if a buyer makes an infinite number of random purchases, she matches with every seller almost surely. In other words, $g(i;j)$ is more left-skewed for small buyers, i.e., smaller buyers have *relatively* greater probability of matching with big sellers. Thus, the expected average out-degree of sellers that a buyer matches is adversely correlated with her size and, as a result, with her connections. (Fact 4).¹²

3.5 Hierarchy

As emphasized in the literature, negative degree assortativity does not mean that well-connected sellers only sell to poorly-connected buyers. The most productive firms typically sell to a broader range of buyers, from the most productive (best connected) down to the least productive (less connected). Low-productivity sellers, on the other hand, only connect with high-productivity buyers (Bernard and Moxnes, 2018). At first glance, this appears to be strong support for fixed-cost hierarchy models, where only firms with significant economic scale can overcome fixed costs and profitably engage with small partners.

However, this finding also arises naturally from the elementary model. The best way to demonstrate this is to construct a coupling, which we do in the next section, so here we focus on the intuition. The key is to recognize that although a seller with greater S is more likely to match *any* buyer, it is *relatively* more likely to match small buyers. The intuition is essentially the same as that underpinning negative degree assortativity. For example, consider two buyers with $b_1 = 1; b_2 = 100$, as well as a seller with $s = 0.01$. The seller has 1% chance of matching with the first buyer, and $1 - 0.99^{100} \approx 100\%$ chance of matching with the second. In contrast, when S is close to 1, the matching probability for both buyers

¹²The formal proof is presented in Appendix A.2. In the next section, we also show that this correlation persists with aggregation, matching the finding of Serrano and Boguná (2003) that the partners of well-connected countries are, on average, less-well connected themselves.

is approximately equal to one. While both sellers are quite likely to match with the large buyer, the large seller has a significantly higher probability of matching with the smaller buyer (Fact 5).

4 Generalization

The previous section introduced the elementary model and showed how it matches existing stylized facts on production networks. We now introduce the general properties of the elementary model, characterizing the *families* of statistics it produces. Data on production networks are usually quite detailed, hence the number of relationships or variable combinations studied by researchers can grow quickly. Rather than exhausting all combinations in a dataset and checking the corresponding predictions of the elementary model one at a time, it is useful to characterize general predictions of the model, pinning down the corresponding prediction for *any* empirical fact in a given statistic family. Then researchers can easily employ these results to compare new empirical regularities from their data with those generated by the elementary model.

We consider three choices confronting researchers deciding how to present empirical characteristics of their data. (1) What statistical transformation should be applied? In particular, we examine three classes of statistical transformations: monotone statistics, order statistics, and higher order relationships. (2) What level of aggregation should be considered? Depending on the question, the researcher might be interested in transactions, firm-level variables or even country-level aggregates. (3) What variables of interest should be examined and how should they be linked? The fundamental of the elementary model is a firm-to-firm transaction but studies might be interested in characterizing the network based on firm productivity or other variables. We explore the general properties of the elementary model along these three dimensions.

4.1 Ranking and Stochastic Dominance Theorems

When dealing with probabilistic models, the ranking theorem and stochastic dominance theorem are useful tools to facilitate the analysis. Both theorems, in a broad sense, allow us to compare random variables in the same way that we compare deterministic variables. We first introduce these two theorems:

Ranking Theorem. *Cumulative G^X first-order stochastically dominates (FSD) cumulative G^Y if and only if for any increasing and piecewise differentiable function $u(z)$,*

$$E_{G^X}[u(z)] > E_{G^Y}[u(z)]:$$

Let \succsim denote first-order stochastic dominance. If there are two random variables such that $X \succsim Y$, we also refer to X and Y as *statistically ordered in FSD*. Intuitively, the ranking theorem tells us the stochastic ordering (in the first-order sense) of two random variables is preserved with monotonically increasing transformations.

Stochastic Dominance Theorem. *The random variable $X \succsim Y$ if and only if there is a coupling $(\hat{X}; \hat{Y})$ of X and Y such that*

$$P[\hat{X} \leq \hat{Y}] = 1;$$

which holds with inequality for some values. We refer to $(\hat{X}; \hat{Y})$ as a monotone coupling of X and Y .

A coupling of X and Y , $(\hat{X}; \hat{Y})$, is a joint probability space with its marginal distributions being X and Y . Not surprisingly, there could be many ways to construct such a probability space. The right-to-left direction of stochastic dominance theorem says that if we can find such a probability space, with $\hat{X} \leq \hat{Y}$ being a sure event, then we know that $X \succsim Y$. The left-to-right direction of the theorem says that if $X \succsim Y$, there always exists a coupling $(\hat{X}; \hat{Y})$ such that $\hat{X} \leq \hat{Y}$ surely.

Intuitively, under random allocation, buyer- and seller-statistics derived from the model are also random variables. When we use the notion of first order stochastic dominance to compare random variables, we are anchoring *values* and comparing *probabilities*. The stochastic dominance theorem, on the other hand, allows us to translate the problem to anchoring *probabilities* and comparing *values*. Economic models usually apply functional transformations on the value side, hence when using the stochastic dominance theorem, we do not need to alter the anchoring every time when making comparisons. As a result, we can perform comparative statics for probabilistic models in the same way that we do for deterministic models. For the interested readers, we provide a more detailed explanation of the coupling method and its relation to the stochastic dominance theorem with examples in Appendix A.1.

4.2 General Statistical Transformations

4.2.1 Monotone Statistics

Denote the assignment result of seller i by $\mathbf{x}_i^S = (x_{i1}, \dots, x_{iM}) \in \mathbb{N}^M$, and let $t: \mathbb{R}^M \rightarrow \mathbb{R}$ be some statistical function of \mathbf{x}_i^S .¹³ Consider two sellers i and i^0 , with $S_i > S_{i^0}$. We can couple \mathbf{x}_i^S and $\mathbf{x}_{i^0}^S$ in the following way: first, set $\hat{\mathbf{x}}_{i^0}^S = \mathbf{x}_{i^0}^S$. Then, set $\hat{\mathbf{x}}_i^S$ as the sum of two random vectors: the first random vector equals $\hat{\mathbf{x}}_{i^0}^S$ with probability one, and the second random vector is generated independently according to the distribution of $\mathbf{x}_{i^0}^S$ with $S_{i^0} = S_i - S_{i^0}$.¹⁴ That is, $\hat{\mathbf{x}}_i^S = \hat{\mathbf{x}}_{i^0}^S + \mathbf{x}_{i^0}^S$. Intuitively, the realization of purchases to seller (bin) i can always be viewed as the union of the realizations in two smaller-sized bins; one with size S_{i^0} and the other with size $S_i - S_{i^0}$.

Then, instead of directly comparing the statistics of \mathbf{x}_i^S and $\mathbf{x}_{i^0}^S$, we only need to compare the statistics of their coupling. Note that by construction, $(\hat{\mathbf{x}}_i^S; \hat{\mathbf{x}}_{i^0}^S)$ is a monotone coupling of \mathbf{x}_i^S and $\mathbf{x}_{i^0}^S$. Therefore, for any monotonic t , $(t(\hat{\mathbf{x}}_i^S); t(\hat{\mathbf{x}}_{i^0}^S))$ is also a monotone coupling of $t(\mathbf{x}_i^S)$ and $t(\mathbf{x}_{i^0}^S)$. This greatly simplifies the analysis because instead of computing the exact distribution for every statistic t that we are interested in, we only need to examine the monotonicity of t . Then, we can directly apply the stochastic dominance theorem to determine the stochastic ordering of $t(\mathbf{x}_i^S); t(\mathbf{x}_{i^0}^S)$.

For example, consider the number of buyers that seller i matches with, which we denote by n_i^S . The random variable n_i^S is generated from the following statistical transformation: $t_1(\mathbf{x}_i^S) = \sum_j 1_{x_{ij} > 0}$. It is trivial to show that $t_1(\hat{\mathbf{x}}_i^S + \hat{\mathbf{x}}_{i^0}^S) \geq t_1(\hat{\mathbf{x}}_{i^0}^S)$ because the realized number of balls from each buyer can only weakly increase when we add the realization of $\mathbf{x}_{i^0}^S$. Therefore by construction,

$$P[n_i^S \geq n_{i^0}^S] = 1.$$

By the stochastic dominance theorem, we then have $n_i^S \geq n_{i^0}^S$. The ranking theorem subsequently implies that $N_i^S > N_{i^0}^S$.

Formally, given two random vectors $\mathbf{X}, \mathbf{Y} \geq \mathbf{0}$,¹⁵ a statistical transformation t is said

¹³To save notation, throughout the paper, we use t to refer a general statistical transformation and $t_1; t_2; \dots$ to denote specific statistical transformations (functional forms are specified in the paper) regardless the dimension of the input vector.

¹⁴Two random vectors are said to be *equal* if they are equal as functions on their probability space. If two random vectors \mathbf{X} and \mathbf{Y} are equal in distribution and $\text{corr}(\mathbf{X}; \mathbf{Y}) = 1$, we say that \mathbf{X} and \mathbf{Y} are *equal with probability one*, or $\mathbf{X} = \mathbf{Y}$.

¹⁵We follow the convention to express vector inequality in the following way: any two vectors $\mathbf{X} \leq (=) \mathbf{Y}$ means that each component of vector \mathbf{X} is less (greater) than or equal to each corresponding component of

to be *monotonically increasing* if $t(\mathbf{X} + \mathbf{Y}) \geq t(\mathbf{X})$ for any realization of \mathbf{X} , \mathbf{Y} , which holds with strict inequality for some realizations. Similarly, t is said to be *monotonically decreasing* if $t(\mathbf{X} + \mathbf{Y}) \leq t(\mathbf{X})$. We then summarize the result in the following proposition:

PROPOSITION 1. *For $s_i > s_{i^0}$, $t(\mathbf{x}_i^s) \geq t(\mathbf{x}_{i^0}^s)$ if t is a monotonically increasing transformation; $t(\mathbf{x}_{i^0}^s) \geq t(\mathbf{x}_i^s)$ if t is a monotonically decreasing transformation.*

Applying proposition 1, it is immediate that the size of the largest buyer that seller i matches with *FSD* that with which seller i^0 matches. In contrast, the size of the smallest buyer that seller i^0 matches with *FSD* that with which seller i matches. As a result, we will always find that larger sellers match with more dispersed buyers.¹⁶

We construct the coupling on the buyer side in a similar way. Denote the assignment result of buyer j by $\mathbf{x}_j^b = (x_{1j}; \dots; x_{Nj}) \geq \mathbf{0}^N$. Consider two buyers, j and j^0 , with $b_j > b_{j^0}$. First set $\hat{\mathbf{x}}_{j^0}^b = \mathbf{x}_{j^0}^b$. Then, let $\hat{\mathbf{x}}_j^b$ equal the sum of two random vectors: one equals $\hat{\mathbf{x}}_{j^0}^b$ with probability one, and the other is generated independently according to the distribution of $\mathbf{x}_{j^0}^b$ with $b_{j^0} = b_j - b_{j^0}$. Intuitively, as purchases are not ordered, making b_j purchases can always be viewed as one first make b_{j^0} and then the other $b_j - b_{j^0}$ purchases. Then, the following proposition is immediate:

PROPOSITION 2. *For $b_j > b_{j^0}$, $t(\mathbf{x}_j^b) \geq t(\mathbf{x}_{j^0}^b)$ if t is a monotonically increasing transformation; $t(\mathbf{x}_{j^0}^b) \geq t(\mathbf{x}_j^b)$ if t is a monotonically decreasing transformation.*

4.2.2 Order Statistics

Next, we consider another class of commonly used statistical transformations: order statistics. Most order-statistic functions, such as quantiles or percentiles, are not monotone. Nevertheless, given our environment, the sample average of these statistics can be easily ordered. We use percentiles to illustrate the point. One can construct similar proofs to examine other order statistics and the associated rank statistics.

vector \mathbf{Y} . If $\mathbf{X} \succeq \mathbf{Y}$, it means that $\mathbf{X} \geq \mathbf{Y}$ and $\mathbf{X} \neq \mathbf{Y}$.

¹⁶It should be noted that in practice, all empirical correlations are calculated using actual assignments rather than expected assignments. When comparing firms based on realized assignments, the sufficient condition for our results to hold is that the variable of interest in the x-axis must follow a monotonic probability ratio ordering (*MPR*), a condition that is stronger than first-order stochastic ordering but weaker than monotonic likelihood ordering (Eeckhoudt and Gollier, 1995). Reassuringly, with the elementary model, all x-axis statistics used in the literature to date satisfy this condition. We present the formal proof as a robustness check in Section A.5.

Without loss of generality, consider the i -th percentile buyer of seller i . Let $r(\alpha; i)$ denote its expected rank. Obviously, $r(\alpha; i)$ is an increasing function of α : higher the percentile, by definition we refer to the larger-valued buyer in the matched list. Denote $F_i(z) := \frac{\sum_{j=1}^z p_{ij}}{\sum_j p_{ij}}$ as the expected fraction of buyers whose rank is smaller than z . By definition, $r(\alpha; i) = z$, and the inverse function $r^{-1}(z; i)$ is also an increasing function.

Let $g(j; i) := \frac{p_{ij}}{\sum_j p_{ij}}$. Just as $g(i; j)$ has the monotone likelihood ratio (*MLR*) property proved in Section A.2, it is easy to verify that $g(j; i)$ also has the monotone likelihood ratio (*MLR*) property and hence can be *FSD* ordered in i . Therefore, it is immediate that $F_{i^0} z \geq F_i z$ for all z by the definition of *FSD*, i.e., the expected fraction of buyers that are below an arbitrary rank is always greater for large sellers. By definition $r^{-1}(z; i) := F_i^{-1}(z)$, hence it is immediate that $r^{-1}(z; i) \geq r^{-1}(z; i^0)$. Combining this with the fact that $r^{-1}(z)$ increases in z , we conclude that $r(\alpha; i) \geq r(\alpha; i^0)$ for all α . A similar proof can be constructed for buyers.

PROPOSITION 3. *The average rank of the i -th percentile buyer (seller) that a seller (buyer) matches with decreases in seller (buyer) size.*

Intuitively, if a seller increases its size, it becomes more likely to match with every buyer, but more importantly, it becomes relatively more likely to match with smaller buyers. This pushes up every existing buyer's percentile, which in turn means for a given percentile, the expected rank of its associated buyer decreases.

4.2.3 Higher-order Relationships

Production network properties are often described by higher-order relationships. The degree assortativity discussed in the previous section is one example, but researchers might want to look at other characteristics other than degree and higher-order relationships beyond the second-order. In this subsection, we show how to pin down the elementary-model predictions on higher-order relationship statistics in general.

The trick is to note that a higher-order statistic can be viewed as the composition of a series of statistical transformations. Thus, we can construct a statistic generating function for k -th-order relationships. Let $k_t(\cdot)$ describe the k -th-order statistics given a statistical function t . This function applies to both buyers and sellers with a slight abuse of notation: when $t = i$, the statistics are calculated for a seller, and when $t = j$, they are calculated

for a buyer. We use t to denote partners on the other side of the relationship: when t refers to a seller, then t^{-1} refers to a buyer and vice versa. The variable \mathbf{x} describes the assignment result. Then, the function $k_t(\cdot)$ can be constructed as:

$$k_t(\cdot) = \begin{cases} E(t(\mathbf{x})) & \text{if } k = 1; \\ \frac{\sum \frac{k_t^{-1}(\cdot) \rho}{\sum \rho}} = \sum k_t^{-1}(\cdot) g(\cdot; \cdot) & \text{if } k > 1: \end{cases}$$

For instance, let $t_1(\mathbf{x}) = \sum 1_{\mathbf{x} > 0}$, where \mathbf{x} refers to the realized assignment for i . Buyer j 's expected connectivity can therefore be written as $k_{t_1}^1(j)$, and the expected average connectivity of its matched seller is $k_{t_1}^2(j)$. Generally speaking, assortativity is nothing but a correlation between one second-order and one first-order statistic.

Recall that the distribution $g(i; j^\theta)$ FSD $g(i; j)$ when $b_j > b_{j^\theta}$, and the distribution $g(j; i^\theta)$ FSD $g(j; i)$ when $s_i > s_{i^\theta}$. By iteration, we arrive at the following proposition:

PROPOSITION 4. *Let $k_t(\cdot)$ and $k_{t^\theta}(\cdot)$ be two higher-order relation statistics across buyers (or sellers). When both transformations t and t^θ are monotonically increasing or decreasing, $k_t(\cdot)$ and $k_{t^\theta}(\cdot)$ are positively associated if $(-1)^{k+k^\theta} = 1$ and negatively associated if $(-1)^{k+k^\theta} = -1$. When one of t and t^θ is monotonically increasing and the other is monotonically decreasing, $k_t(\cdot)$ and $k_{t^\theta}(\cdot)$ are positively associated if $(-1)^{k+k^\theta} = -1$ and negatively associated if $(-1)^{k+k^\theta} = 1$.*

For example, consider the out-degree of sellers against the expected average in-degree of buyers with which sellers match. The latter is given by:

$$\bar{N}^b(i) = \frac{\sum_j N_j^b \rho_{ij}}{\sum_j \rho_{ij}} := \sum_j N_j^b g(j; i) = E_{G_i}(N_j^b):$$

By definition $\bar{N}^b(i) := k_{t_1}^2(i)$ and $\bar{N}_i^s := k_{t_1}^1(i)$. Since t_1 is monotonically increasing, and $k + k^\theta = 3$, from proposition 4 we immediately know that sellers' connections also exhibit negative assortativity, i.e, the average customer of a highly connected seller purchases from a relatively small number of suppliers.

We can also view $k_t(\cdot)$ as a $g(\cdot; \cdot)$ -weighted sum of $k_t^{-1}(\cdot)$. In some cases, one may want to use weighting functions other than $g(\cdot; \cdot)$. Similar to the above analysis, we can pin down the correlation between the higher-order statistics by examining the monotonicity of associated statistical transformations and the weighting function.

4.3 Arbitrary Aggregation

In the elementary model, any relationship that holds at the disaggregated level is maintained with aggregation. Because we can always view a set of buyers (denote the set by I) as one buyer with $\sum_{j \in I} b_j$ purchases and a set of sellers (denote the set by I^0) as one seller whose size given by $\sum_{i \in I^0} s_i$. This yields our next proposition:

PROPOSITION 5. *Relationships that hold at a disaggregated level are preserved under aggregation in the elementary model.*

Consider for example the firm-level statistics at the intensive margin. As buyers are independent, the total number of purchases that fall into seller i also follows a binomial distribution:

$$P[x_i = x] := P\left[\sum_j x_{ij} = x\right] = C_{\sum_j b_j}^x s_i^x (1 - s_i)^{\sum_j b_j - x}. \quad (8)$$

The sum of independent binomial random variables is itself a binomial random variable if they share the same success probability. Therefore the probability of x purchases falling into i is identical to $P[x_{iJ} = x]$, where the representative buyer J has $\sum_j b_j$ purchases. The ordering of sales at the bilateral level preserves at the firm level; firms with higher s_i on average not only sell more to each buyer but also have greater total sales. Similarly, countries with higher sales also sell to more destinations and sell more to each destination.

4.4 General Variables of Interest

The elementary model essentially generates only one outcome: the realization of purchase assignment $f_{X_{ij}} g_{N \setminus M}$. Therefore, all statistical relationships that the model can directly match are necessary functions of $f_{X_{ij}} g_{N \setminus M}$. However, we are sometimes interested in characterizing the network based on other firm features, such as productivity or R&D intensity. If, in the data, a more productive buyer matches, on average, with less productive sellers, we want to know whether this empirical regularity informs us about the underlying matching mechanism.

We formalize the question as follows: let the buyer-seller assignment follow the elementary model, and consider a firm-specific variable of interest, \cdot . Under which data generating process can $f \cdot g$ be *FSD* ordered in \cdot , so that the results of the previous subsections could be applied immediately?

Clearly, if (1) is a monotone deterministic function of or (2) is *FSD* generated in , that $f \succ g$ can be *FSD* ordered in is trivially true. Moreover, if (3) is a monotone deterministic function of the realizations of t , where t can be any transformation of $f(x_{ij})g_{N \times M}$ that has an *FSD* order or (4) is *FSD* generated based on such a t , $f \succ g$ is also *FSD* ordered in (either in ascending or descending order). The proof is trivial using the ranking theorem and the stochastic dominance theorem.

Take productivity as an example. One example of case (1) are models where firm size is an increasing function of productivity. Case (2) includes models where the productivity distributions of small and large firms are allowed to overlap, but larger firms have a greater probability of being more productive. If we consider an environment where firms' productivity is a function of their realized sourcing outcomes $\mathbf{x}_j^b = (x_{1j}^b, \dots, x_{nj}^b)$ and productivity is a non-decreasing transformation of \mathbf{x}_j^b , it belongs to case (3). Finally, if a firm's productivity is not a deterministic function of its realized sourcing outcomes but a stochastic one following an *FSD* ordering, it corresponds to case (4). The settings of Melitz (2003), Bernard et al. (2003), and Antras et al. (2017) can be viewed as examples of (1), (2), and (3), respectively.

If productivity falls into one of the above four data generating processes, the elementary model predicts, for example, that more productive buyers will match with less *productive* sellers on average. Consequently, we will not be able to draw any conclusions about how firm matching behaviors differ depending on productivity. To summarize, if a general variable of interest is stochastically monotone in fundamental model parameters or in realized variables that follow a *FSD* ordering, it provides no additional information about firm matching relative to the elementary model.

5 Linking to Economics

One argument on the limitation of random-allocation models, such as the one proposed by Armenter and Koren (2014), is that they are statistical models lacking economics. Section 5.1 shows that the elementary model can be derived from a competitive environment, where models with an EK structure are a special case. This finding in turn greatly improves our ability to map the elementary model to data for economic analysis, which we demonstrate with examples in Section 5.2.

5.1 Elementary Model from a Competitive Environment

Consider an environment where buyers choose the seller that provides the highest utility for each of their purchases. Buyer preferences over seller i 's product are drawn from a distribution H_i and denoted by \mathbf{v}_i . The distributions $H_1; \dots; H_N$ are independent, admissible, and *FSD* ordered. We can view H as a function of some model primitives, such as various product characteristics, including price.

Intuitively, $H_i \succ H_{j^0}$ implies that i always has a higher probability of receiving better utility draws; hence, its probability of being chosen is always higher in the competitive equilibrium. Given the setting, the probability that a purchase goes to seller i is given by:

$$s_i = \mathbb{P}[\mathbf{v}_i > \max(\mathbf{v}_{(-i)})];$$

where $\mathbf{v}_{(-i)}$ is the vector of $N - 1$ random variables excluding \mathbf{v}_i . For simplicity, let us focus on the case in which H_i is continuous and differentiable for all i . Consider two sellers, $H_i \succ H_{j^0}$, then we have

$$s_i := \mathbb{P}[\mathbf{v}_i > \max(\mathbf{v}_{(-i)})] = \mathbb{P}[\mathbf{v}_i > \max(\mathbf{v}_{(i;j^0)})] \mathbb{P}[\mathbf{v}_i > \mathbf{v}_{j^0}];$$

Note that $\max(\mathbf{v}_{(i;j^0)})$ is also a random variable. Let $J_{(i;j^0)}$ denote its cumulative distribution. Thus,

$$\begin{aligned} \frac{s_i}{s_{j^0}} &= \frac{\mathbb{P}[\mathbf{v}_i > \max(\mathbf{v}_{(i;j^0)})] \mathbb{P}[\mathbf{v}_i > \mathbf{v}_{j^0}]}{\mathbb{P}[\mathbf{v}_{j^0} > \max(\mathbf{v}_{(i;j^0)})] \mathbb{P}[\mathbf{v}_{j^0} > \mathbf{v}_i]} \\ &= \frac{\int_{\gamma}^1 J_{(i;j^0)}(z) dH_i(z) \int_{\gamma}^1 H_{j^0}(z) dH_i(z)}{\int_{\gamma}^1 J_{(i;j^0)}(z) dH_{j^0}(z) \int_{\gamma}^1 H_i(z) dH_{j^0}(z)} \\ &> \frac{\int_{\gamma}^1 J_{(i;j^0)}(z) dH_i(z) \int_{\gamma}^1 H_i(z) dH_i(z)}{\int_{\gamma}^1 J_{(i;j^0)}(z) dH_{j^0}(z) \int_{\gamma}^1 H_i(z) dH_{j^0}(z)}, \end{aligned}$$

where the inequality is ensured by $H_i(z) < H_{j^0}(z)$. In addition, by $H_i \succ H_{j^0}$ and both $J_{(i;j^0)}(z)$ and $H_i(z)$ being increasing in z , the ranking theorem implies that both fractions on the right hand side (RHS) of the above expression are larger than 1. Therefore, $s_i > s_{j^0}$.

Note that the competitive-selection environment described above is the same as in EK. The Fréchet distribution is just one of many distributions that satisfy the *FSD*-ordering property: if one Fréchet distribution has the same shape parameter but a greater level

parameter than another Fréchet, the former FSD the latter. When assuming that H_i follows the Fréchet distribution, the probability of a seller i matching a buyer j for a transaction in our model gives exactly the same expression as the probability that country i provides a good at the lowest price in country j in the EK model. With additional assumptions on the utility function and continuity, the model will collapse to EK, with sellers being isomorphic to exporting countries in the EK model.¹⁷

The above analysis shows that the elementary model can be derived from a competitive environment, where models with an EK structure are a special case. This finding in turn greatly improves our ability to map the elementary model to data for economic analysis, which we demonstrate with examples in Section 5.2.¹⁸

5.2 Linking the Model to Data: Design Matters

As random-allocation can be viewed as an economic instead of a purely statistical process, this in turn disciplines how we should link the model to data when analyzing certain economic problems. To illustrate this point we provide two examples with existing balls-and-bins designs: the examination of negative degree assortativity in Bernard et al. (2018a) and the analysis of the fraction of exporting firms by Armenter and Koren (2014).

In their paper on two-sided heterogeneity and exporter-importer matching, Bernard et al. (2018a) ask if the negative degree assortativity among Norwegian exporters and Swedish importers can be captured by a simple balls-and-bins model. They conclude that a balls-and-bins model does not produce negative assortativity and use that result to argue in favor of a model with match-specific fixed costs. However, we find negative assortativity in the Norwegian trade data by treating each transaction as a ball and assigning these balls randomly according to the elementary model, as shown in Figure 1.¹⁹

¹⁷If one foregoes continuity but adds additional assumptions such as Bertrand competition, the model arrives at Eaton et al. (2013) (EKS). Although not the focus of this paper, it is clear from these two examples (EK and EKS) that the elementary model matches buyer-seller data neither necessary nor sufficient to guarantee novel implications for aggregate welfare or productivity. Whether Hulten’s theorem holds exactly, or whether the sufficient statistic on the gains from trade change, depends on other assumptions and modelling elements researchers bring to aggregate their model.

¹⁸The above analysis also implies that it is possible to reformulate or rewrite richer theories of production networks as an extension or variation of the elementary model. For example, theories featuring suppliers’ selection by buyers (Panigrahi, 2022; Miyauchi, 2021), endogenous search intensity (Chaney, 2014; Arkolakis et al., 2021; Demir et al., 2021; Huang et al., 2021), and relation-specific fixed cost (Bernard et al., 2018a; Lim, 2020; Huneus, 2019; Zou, 2020; Dhyne et al., 2021). Thanks to Yuhei Miyauchi for bringing this to our attention.

¹⁹The Norwegian trade data is described in Appendix B.1. Bernard et al. (2018a) had access to import-

Notes: This figure shows on the x-axis all possible values of the number of suppliers per firm and on the y-axis the average number of customer connections of these suppliers, using the simulated buyer-seller network based on Norwegian customs data from 2005. In particular, the total number of transactions of each buyer and seller is taken as given, but these transactions are randomly redistributed between buyers and sellers according to the elementary model. The units of the axes are in logarithmic. The fitted regression lines and 95% confidence intervals are indicated by the solid line and the gray area.

Figure 1: Degree assortativity with the correct falsification design: Norwegian data

The source of difference lies in their exercise design. Bernard et al. (2018a) consider $N = M$ bins, with N being the number of exporters from Norway and M being the number of importers from Sweden. Each bin size is set as the product of the relative degree of the buyer and seller: $\hat{n}_i^s = \frac{n_i^s}{\sum_i n_i^s}$, $\hat{n}_j^b = \frac{n_j^b}{\sum_j n_j^b}$, and $s_i = \hat{n}_i^s \hat{n}_j^b$. The total number of balls from Sweden is set as the total number of existing connections: $n = \sum_i n_i^s = \sum_j n_j^b$. The balls are then assumed to be assigned to bins at random, with the probability of any ball landing on a bin i being s_i .

There is an immediate problem with this setup. If a ball is a connection, once a ball has landed in a bin (an importer-exporter pair) that bin should be closed. Instead they allow bins to catch more than one ball. As a result, the model-simulated expected number of connections does not, by construction, match the sample mean, which renders inconsistency in the model design in the first place.²⁰ This example emphasizes the importance of a correctly designed balls-and-bins model in assessing empirical regularities of the data.

Armenter and Koren (2014) is the first and most well-known example of a balls and bins model in international trade. The paper examined, among other things, how well such

exporter trade data aggregated to the annual level rather than the underlying transaction data. We use the transaction-level sales by Norwegian exporting firms to foreign importing firms. Sweden is the largest destination for Norwegian exports.

²⁰To see this more clearly, if we plug the balls and bins' sizes into the statistical function for the extensive margin, it is immediate that the design implicitly requires that $E(n_i^s) = E(\rho_{ij}) = E(\sum_i ((1 - (1 - \frac{n_i^s n_j^b}{n^2})^n)))$, which does not hold in general.

a model captures the fraction of US firms that export. Each US manufacturing firm was modeled as a seller throwing balls (i.e., sales) into two bins (i.e., buyers), one domestic and one international. The number of balls of each firm was set to equal its total sales divided by the average US export shipment size, which is \$36,000. The relative size of the two bins is set to equal their proportionate share of US manufacturer purchases. Armenter and Koren (2014) simulated 297,873 US firms with a size distribution approximated by a log-normal distribution with $\sigma = 2.66$ and $\mu = 13.2$. Given this setup, they find that 74% of US manufacturing firms export, in sharp contrast to the 18% in the US data.

Starting from the elementary model, we reexamine the question of how many US manufacturing firms export. We assume the same distribution of US firm sizes as Armenter and Koren (2014) and maintain their assumption that US firms throw balls at domestic and foreign customers.²¹ However, we consider several adjustments to their setup. In addition to two aggregate buyers bins (domestic and foreign), we consider simulations with country-level bins and with firm-level bins. With country-level bins, each bin is proportional to the share of country purchases from the US. For the firm-level bins, each bin size should ideally be each firm’s share of US purchases. We impute this information by assuming that the relative firm size distribution in the buying countries follows the size distribution of Chinese importing firms.²² Linking to economics, the elementary model with balls representing transactions and bins as foreign firms is our preferred design, as the positive transactions between firms are recorded in customs data and are the basis of trade statistics.

There are two additional important choices to be made in designing the balls and bins framework. The first is the ball size and second is the presence and level of any cutoff which limits what transactions are recorded in the data. Armenter and Koren (2014) assumed that each ball represented \$36000 of sales, the average transaction size in the US export data, and imposed no cutoff. The US data have a minimum transaction size of \$2000, i.e. a cutoff below which export transactions are not systematically recorded. We consider balls of three sizes: \$36000, \$2000, and \$100, where \$100 is the minimum international

²¹Simulation exercises assuming importers throw balls are reported in Appendix Table A1. The results change very little.

²²In the case of China, we take the actual distribution from Chinese customs data for the same year. Then each Chinese firm’s bin size is S_{china} *import share of that firm, yielding n_{china} bins whose distribution is A . For other countries, we assume their importer bin distribution is the same as that of China. For example, if country j ’s total manufacturing imports from US are twice as large as China’s, we randomly draw $2*n_{china}$ bins from A so that the sum over all foreign firms and countries equals the share of US manufacturing that is exported. Armenter and Koren (2014) did not have access to data on foreign firm (buyer) sizes or shares.

Table 1: Share of Manufacturing Exporters in the US: balls and bins Simulations

<i>US Firms as Ball Holders</i>						
<i>Bins are</i>	<i>US Customs Reporting Cutoff</i>					
	2000 USD (DATA)			36000 USD (AK)		
	Firms	Countries	RoW as one bin	Firms	Countries	RoW as one bin
	(1)	(2)	(3)	(4)	(5)	(6)
<i>Ball Size = 100USD</i>	11.02 %	79.22 %	90.72 %	0.41 %	38.51 %	59.84 %
<i>Ball Size = Cutoff Size</i>	92.34 %	92.05 %	92.85 %	65.38 %	64.32 %	<u>66.95 % (AK)</u>

Notes: Each number in this table is the share of direct exporters among US manufacturing firms calculated from a separate balls and bins simulation of a random allocation model. Bin size (buyer), ball size (transaction) and the import reporting cutoff vary across the cells.

transaction size observed in Norwegian customs data. We prefer \$100-sized balls with an export recording cutoff of \$2,000, as this matches the empirical context. We recognize that the “true” minimum export transaction size is likely larger than \$100, but use this to demonstrate the importance of hidden assumptions in comparing the model to data.

The results of this exercise are intuitive and important for the design of balls-and-bins models for particular data applications. As reported in Table 1, in our preferred design, the model predicts 11% of US manufacturing firms export, which is much closer to the 18% in the data. With aggregate or country-level bins, the model performs poorly in matching the US exporter share regardless of ball size and the presence of a cutoff. This implies that in order to match the low fraction of US exporters, there must be firm heterogeneity in both buyers and sellers. This, of course, is at the heart of the recent literature on production networks. The recording cutoff also matters in this particular case, e.g. a \$10,000 transaction is not the same as a collection of 100 \$100 transactions. Not knowing the true distribution of transactions can once again cause the model to overestimate the share of exporting firms.

These two examples highlight the importance of careful model design and the relevance of assumptions when taking a balls-and-bins model to the data, and the benefits of the results presented in Section 5.1.

6 Data Response to Shocks

The elementary model, in addition to matching cross-sectional stylized facts in production and trade networks, can guide our understanding of a diverse set of network responses to shocks. In other words, empirical regularities, not only in levels but also in changes, may not improve our understanding of firm interactions beyond random matching. We present

two examples, one examining the reshuffling of importer-exporter links following the arrival of new suppliers, and the other looking at firm-level responses to exchange rate shocks.

6.1 Bipartite Outcomes

The elementary model is well-designed to understand the pattern of partner switching in response to shocks. Consider Sugita et al. (forthcoming), who combine several existing network-formation mechanisms to explain how US textile and apparel buyers match with Mexican exporters after the end of the Multi-Fibre Arrangement (MFA) and the ensuing arrival of new Chinese exporters.

Sugita et al. (forthcoming) cite five empirical findings that motivate and support their model of firm-to-firm matching. When MFA quotas are removed from their products, (1) US importers upgrade their Mexican partners more often and (2) Mexican exporters downgrade their US partners more often; (3) Among firms that switch their main partners, the new partners' ranks positively correlate with the ranks of the old partners; (4) The capability cutoff for Mexican exporters increases more if the products had quotas removed; (5) U.S. importers and Mexican exporters decrease the number of partners in each other's countries.

However, all of these five findings can be generated from the elementary model. First, (3) is trivially true in a random matching world. As links are formed randomly, new partners should follow the same distribution as the old partners – in fact they should even have the same mean ranks in the absence of shocks. Next, we consider the same shock as the authors do: the end of the MFA put competitive pressure on Mexican firms as it led to an increased entry of Chinese sellers to the US economy. Through the lens of the elementary model, this implies that the normalized size of Mexican sellers decreases from s_i to $\frac{s_i}{\lambda}$, where $\lambda > 1$. The finding (5) is immediate: reduced bins size means fewer matches between US buyers and Mexican sellers.

Sugita et al. (forthcoming) ranked firms based on their product-level trade values prior to the liberalization; hence, their *firm rank* is directly comparable to our s and b . The *partner rank* is computed as the rank of the firm's largest partner. Correspondingly, let \bar{j}_i denote the highest-ranked buyer that seller i matches with in the elementary model. Recall that when $s_i > s_{i^0}$, the largest buyer that seller i matches with FSD the largest buyer with which i^0 matches. Let $s_{i^0} = \frac{s_i}{\lambda}$; we immediately have that $E_{preMPA}(\bar{j}_i) > E_{postMPA}(\bar{j}_i)$: exporters in Mexico experience partner downgrading.

Similarly, denote \bar{i}_j as the size of the highest-ranked seller with which buyer j matches. Applying the inclusion-exclusion principle, the probability that $\bar{i}_j \geq z$ conditional on the buyer purchasing from Mexico is

$$P[\bar{i}_j \geq z; \cdot] = \frac{(\sum_{i \geq z} s_i + (1 - \alpha))^{b_j} - (1 - \alpha)^{b_j}}{1 - (1 - \alpha)^{b_j}};$$

where the denominator on the RHS is the unconditional probability of at least one purchase from j landing in Mexico; the numerator is the unconditional probability that balls, if any, land in Mexican bins ranked lower than z netting out the probability that no purchases land in Mexico. Given $b_j > 1$ and $\alpha < 1$, $P[\bar{i}_j \geq z; \cdot]$ is an increasing function in α . Therefore, the distribution of \bar{i}_j when $\alpha = 1$ *FSD* the distribution of \bar{i}_j when $\alpha > 1$. Then, by the ranking theorem, $E_{preMPA}(\bar{i}_j) > E_{postMPA}(\bar{i}_j)$: importers in the US experience partner upgrading.

Finally, we consider (4). Denote \underline{i}_j the lowest-ranked seller that buyer j matches with:

$$P[\underline{i}_j \leq z; \cdot] = \frac{1 - (\sum_{i > z} s_i + (1 - \alpha))^{b_j}}{1 - (1 - \alpha)^{b_j}}.$$

Given $b_j > 1$ and $\alpha < 1$, $P[\underline{i}_j \leq z; \cdot]$ is a decreasing function in α . Therefore, the distribution of \underline{i}_j when $\alpha > 1$ *FSD* is the distribution of \underline{i}_j when $\alpha = 1$. By the ranking theorem, this implies that $E_{preMPA}(\underline{i}_j) < E_{postMPA}(\underline{i}_j)$. Recall that by proposition 5, we can view the US as one buyer. Therefore, the rank cutoff for Mexican exporters increases.

In conclusion, although the empirical findings in Sugita et al. (forthcoming) are robust and intriguing, they can be explained by a much simpler model and therefore may not be helpful in establishing the matching mechanism proposed by the authors.

Because different studies look at different shocks and variables of interest, we cannot provide a general solution recipe. Nevertheless, empirical regularities in changes and levels are both about comparative statics. Therefore, the general results derived in Section 4 can help pin down the elementary model's predictions on firm-to-firm or aggregate responses to policy changes or economic shocks.

6.2 Aggregate Outcomes

The elementary model can also be used understand shock responses at a more aggregate level. For example, researchers are frequently interested in the heterogeneous response of

firms to a common shock in terms of their sales, entry and exit, or pricing. A relatively standard empirical specification that examines the heterogeneous response of firms is:

$$\ln(y_{ict}) = \rho \ln(\epsilon_{ct}) + \rho \ln(a_{it-1}) + \rho \ln(a_{it-1}) \ln(\epsilon_{ct}) + d_t + d_{ic} + \epsilon_{ijt}$$

where a_{it-1} is a firm-specific characteristic at time $t-1$ and ϵ_{ct} is a destination-specific shock at time t . We are interested in the estimated ρ and ρ . Without loss of generality, the demeaned a_{it-1} , ρ , can be interpreted as the average impact of the shock on y_{ict} .

Consider, for example, firms' export-volume response to an exchange rate depreciation as in Berman et al. (2012). A fall in the exchange rate is equivalent to all buyers in destination market c increasing the number of purchases from b_j to b_j , where > 1 . Let a_j be a variable of interest that is positively correlated with S_j .

The elementary model implies that firm i 's export quantity to country c , x_{ic} , follows a binomial distribution $Bin(b_c; S_i)$ with $b_c = \sum_{j \in c} b_j$. As $Bin(b_c; S_i) \sim Bin(b_c; S_i)$, it is immediate that

$$\rho = E(\ln(x_{ic}) | b_c) - E(\ln(x_{ic}) | b_c) > 0:$$

Next, we examine the heterogeneous response. Ignoring the untreated countries for now and using the Delta method, one can show that

$$\frac{\partial^2 E(\log(x_{ij}))}{\partial b_j \partial S_i} = \frac{2b_j^2 S_i - 2b_j^2(1 - S_i)}{(2b_j^2 S_i)^2} = \frac{1}{2b_j^2 S_i^2} < 0:$$

Hence, $\rho < 0$, consistent with Berman et al. (2012)'s first finding that the elasticity of the firm's export volume to an exchange rate change decreases with the performance of the firm. Appendix A.6 provides the formal proof as well as the proof of the similar prediction at the extensive margin.

If suppliers tend to charge larger buyers lower prices, as documented by Morlacco (2020) and Rubens (2020), the elementary model also predicts that the elasticity of the exporter price to the exchange rate change increases with the performance of the firm, consistent with the second finding of Berman et al. (2012).²³ In this example, the firm-level responses are not informative of any heterogeneous pricing-to-market behaviors. Those responses can simply be caused by buyer and seller heterogeneity, coupled with a shock-induced random

²³We treat export price as total export value divided by total export volume, just as how it was measured in Berman et al. (2012).

reshuffling of buyer-seller links. Precisely as Berman et al. (2012) suggested, their findings are consistent with any model in which demand elasticity decreases with firm performance.

This example highlights the usefulness of the elementary model in understanding firm-level responses to shocks and policy changes. As with link reshuffling in the network, heterogeneity *in levels* at the firm-to-firm level can lead to heterogeneous responses (heterogeneity *in changes*) for more aggregate outcomes. The elementary model can thus help identify which features of the data are useful in guiding more elaborate model development and which can be explained by the simple random matching model.

7 “Instructive” Statistics and Theory Selection

Despite the fact that our findings so far suggest that many existing empirical regularities may not be sufficiently informative to guide the associated model construction, it simultaneously implies that the elementary model can be a powerful tool for selecting truly informative statistics and benchmarking more elaborated theories. We illustrate these ideas with examples in this section.

7.1 Use the Elementary Model to Discern Statistics

Intuitively, given that the simple elementary model matches a rich set of statistical relationships on production networks, any stylized facts or empirical regularities that necessitate the development of a more complex model must be those that the elementary model fails to match. From the reduced-form perspective, we sketch two ideas on how to use the elementary model to develop “instructive” statistics and hence guide more elaborate model construction. To be precise, “instructive” statistics are those that provide guidance on model structure and parameters values beyond those obtained in the elementary model.

First, we can design statistics that are by themselves “instructive” in that they do not match those from the elementary model. Then, these statistics can be used directly to inform the nonrandom matching process. Second, related to a suggestion of Armenter and Koren (2014), although the signs of some statistical relationships may not be informative, their magnitudes compared with the predictions from the elementary model can be useful in guiding model construction and model parameters. Obviously, each approach has advantages and downsides. The first approach is conceptually more demanding but it does not

require us to compute any statistics using counterfactual data – a great advantage especially when transaction data is not available. The second idea is easy to implement, but can be sensitive to data features. Below are three examples.

7.1.1 “Instructive Statistic” - Seller market shares

One statistic where the data and the elementary model produce opposite signs is the relationship between the number of customers and the average market share of a seller in those customers. Bernard et al. (2022) show that, in the Belgian domestic production network, large firms with many customers have smaller shares of their customers’ purchases than do smaller firms with fewer customers, i.e. firm outdegree and average market share are negatively correlated.

To determine the relationship in the elementary model, we start by noting that the expected number of customers a seller matches with is given by N_i^S . By the law of iterated expectations, the expected average market share of seller i equals:

$$\bar{M}^b(i) = \frac{\sum_j M_{ij}^b \rho_{ij}}{\sum_j \rho_{ij}} = S_i; \quad (9)$$

where M_{ij}^b denotes the expected market share of seller i in buyer j ’s total purchases. The intuition is simple. The probability that a purchase goes to seller i is S_i . Therefore, regardless of a buyers’ size, its expected share of purchases from i is always S_i , hence so does the average share of purchases. We proved before that N_i^S is an increasing function of S_i ; hence we establish the positive relationship between $\bar{M}^b(i)$ and N_i^S in the elementary model. This moment of the data can give guidance to the construction of a more elaborate model, such as Bernard et al. (2022).

7.1.2 “Instructive Statistic” - Correlated Matches

A second instructive statistic comes from considering intertemporal versions of the elementary model. In the baseline design, the assignments are independent events; therefore, a seller matching with a buyer at time t will not increase their matching probability at time $t + 1$. In the spirit of Chaney (2014), consider the following simple probit regression:

$$P[X_{ij;t+1} | b_j; S_i] = 1[X_{ij;t} > 0] + \Psi(b_{j;t+1}; S_{i;t+1}) + \beta_{ij;t+1}$$

Notes: This figure presents binned scatter plots where we divide Norwegian exporters and international importers into 10 × 10 equally sized bins by log sales and log purchases and calculate the share of connected pairs (p_{ij}) in each bin pair. Panels (a) and (b) show the marginal distribution of p_{ij} for the top 10% and the bottom 10% of sellers and buyers, respectively. Panel (c) is a surface plot of p_{ij} across 10 × 10 bins.

Figure 2: Matching probability: Norwegian trade data

where $1[X_{ij;t} > 0]$ is the matching result of buyer j and seller i at time t . In the baseline random-matching model, the matching probability is a function of buyer and seller size, which should be fully captured by $\Psi(b_{j;t+1}; S_{i;t+1})$.

To test this, we use transaction-level Norwegian customs data from 2005-2010. One unique feature of data is that both buyers and sellers are identified, see Bernard et al. (2018a) for details. Without loss of generality, we only consider sellers from Norway and buyers from China. The variables $b_{j;t+1}$ and $S_{i;t+1}$ are proxied by the yearly logged buyer purchases and logged seller sales, respectively.²⁴ We proxy for $\Psi(b_{j;t+1}; S_{i;t+1})$ with their third-order polynomials with full interactions. The estimated $\hat{\alpha}$ is 2.844 and is statistically significant at the 1% level, suggesting that the formation of the production network is indeed path dependent. The persistence of buyer-seller matches can be an important feature in explaining the structure of production networks, as pointed out by Chaney (2014).²⁵

7.1.3 Informative Magnitudes - Bipartite Network Revisited

Even when the signs of some statistical relationships are not informative, their magnitudes compared with the predictions from the elementary model can be useful. We illustrate this

²⁴We obtain quantitatively similar results when controlling for the number of transactions instead of sales.

²⁵Whether the persistence of buyer-seller matches is an important feature to be included in a production network model depends on the research question. While it is surely an important feature to consider when studying network formation dynamics, section A.3 demonstrates that when the assignments are path dependent, all static bipartite relationships predicted by the elementary model remain robust. Generally speaking, adding the time dimension into the model is equivalent to adding another variable of interest, hence the results regarding general variables of interest in Section 4.4 directly apply. A bipartite relationship that can be explained by the elementary model or its extensions precisely points to the underidentification of models that are designed to explain those stylized facts.

Notes: This figure presents binned scatter plots exactly as in Figure 2 but using the simulated data following the elementary model as in Figure 1.

Figure 3: Matching probability: random-matching simulation

point by examining the matching probability between Norwegian sellers and their international buyers in year 2005. In Figure 2, we group sellers (buyers) into 10 equal-sized bins by log sales (purchases) and present the fraction of buyers and sellers that are matched in real data across bins. With a slight abuse of language but no risk of confusion, we refer to the fraction of matched pairs as the matching probability ρ_{ij} . Panels (a) and (b) are the marginal distribution of ρ_{ij} for the top and bottom 10 percent of sellers and buyers, respectively. Panel (c) presents the surface plot of ρ_{ij} across 10 × 10 bins (y-axis in logs).

In Figure 3, we present the same statistic but use data from the random-matching simulation. Specifically, we take the transactions of each buyer and the total number of transactions of each seller as given from the data but randomly reshuffle the transactions. As shown in Figure 3, overall the elementary model captures the actual matching results well. However, it slightly underpredicts the probability that the smallest buyers match with small sellers and overpredicts the probability that large buyers (sellers) match with sellers (buyers) as shown in Figure 5-a, where we present the prediction errors of the matching probability of the elementary model against the real data. If one wants to study how firms match, these prediction gaps are potentially useful in guiding model construction.

7.2 Use the Elementary Model to Select Theory

Related to the idea presented above, we can use the elementary model as a benchmark to select applied theories. This is a slightly different thought experiment: instead of starting from data and the elementary model to ask whether any information left in the data demands a more elaborated theory to explain, we start from a theory and examine its explanatory power compared to the elementary model. In the simplest case (again, a reduced-form

perspective), one may conclude a model is more desirable if it matches more data features than the elementary model. Here we present a more formal treatment. The idea is intimately associated with the concept of Bayesian model selection. This section will explain why this perspective may be preferable for future production network modeling. Formally addressing the testing and inference problem is beyond the scope of this paper and left for future research.

7.2.1 Model Selection

Where there are several competing theoretical models, Bayesian model selection provides a formal way of evaluating their relative probabilities in light of the data and any prior information available. The basic idea is simple. The evaluation of a model M 's performance in light of the data D is based on the likelihood $P(D \mid M)$. Applying Bayes' theorem to invert the order of conditioning, we obtain the model posterior probability given the data:

$$P(M \mid D) \propto P(M)P(D \mid M)$$

where $P(M)$ is the prior probability assigned to the model itself. Thus the posterior probability is the likelihood under the prior for a specific model choice.

In particular, when comparing two models, M_0 versus M_1 , we can write down the ratio of the posterior probabilities and decompose it into two parts:

$$\frac{P(M_1 \mid D)}{P(M_0 \mid D)} = \underbrace{\frac{P(D \mid M_1)}{P(D \mid M_0)}}_{\text{Bayes Factor}} \underbrace{\frac{P(M_1)}{P(M_0)}}_{\text{Priors}}. \quad (10)$$

Bayes factor, which we denote by B_{01} , is the ratio of the likelihoods of the models. When $B_{01} > 1$ (< 1), it represents an increase (decrease) of the support in favor of model 1 relative to model 0 given the observed data. *Priors* captures the belief about the relative plausibility of the models before the arrival of the data. Specifically, the extent to which we update beliefs over the two models after observing the data is completely summarized by the Bayes factor.

In light of the idea of model selection, we can now think more formally about moving from data to a preferred theory. The extent to which a theory is preferred depends on (1) its relative ability in explaining the data compared to the the alternative theory, (2) the

researcher’s priors over the theory and the alternative.

Thinking about model comparisons from a Bayesian perspective has several attractive features. First, it requires the researcher to think more carefully about “what the model is trying to explain.” That is, what is D ? For example in our context, is a model trying to explain buyer-seller linkages, or just some of the statistical relationships based on these linkages? Second, it also allows for the avoidance of overly complex models through penalize the priors. Finally, it is a more comprehensive concept of model evaluation than the concept of falsifiability, which states that a model can be rejected if it fails to explain some aspects of the data (Popper, 1959). In particular, that a model fails to pass certain falsification tests or to match certain moments in data is not sufficient to lead to rejection. Unless the observations are totally impossible within a model, finding that the data have a small probability given a theory does not say anything about the probability of the theory itself without comparisons to an alternative (Trotta, 2008).

Note that in contrast with the frequentist goodness-of-fit tests, Bayesian model selection highlights that it is pointless to reject a theory unless an alternative is available and fits the observed facts better (Loredo, 1990). In other words, the probability of a theory that makes a correct prediction can increase if the prediction is confirmed by observations, provided competitor theories do not make the same prediction. This lines up with the intuition that a verified prediction lends support to the theory that predicts it. In fact, this is very much in line with how theories in trade are evaluated in reality: for instance Krugman (1980) was the preferred theory for explaining intra-industry trade, because other contemporaneous theories fail to explain it.

We next demonstrate how to select a model with examples. To evaluate an applied model quantitatively requires one to compute the likelihood of the model against that of the elementary model, which is presented in subsection 7.2.2. To evaluate an applied model qualitatively, one can plot the simulated matching from it against that from the elementary model. As an illustrative example for the latter, we compare a Beckerian model featuring positive assortative matching in the spirit of Sugita et al. (forthcoming) with the elementary model in explaining firm-to-firm connections. Using the 2005 transaction-level Norwegian customs data with matched Norwegian exporters and international importers, we take each buyer and seller’s transactions as given. For the elementary model, we match buyers and sellers by random reshuffling these transactions. For the Beckerian model, we simulate the

Notes: This figure presents binned scatter plots exactly as in Figure 2, but using simulated data that link buyers and sellers following a Beckerian matching rule. The data generating process is described in the text.

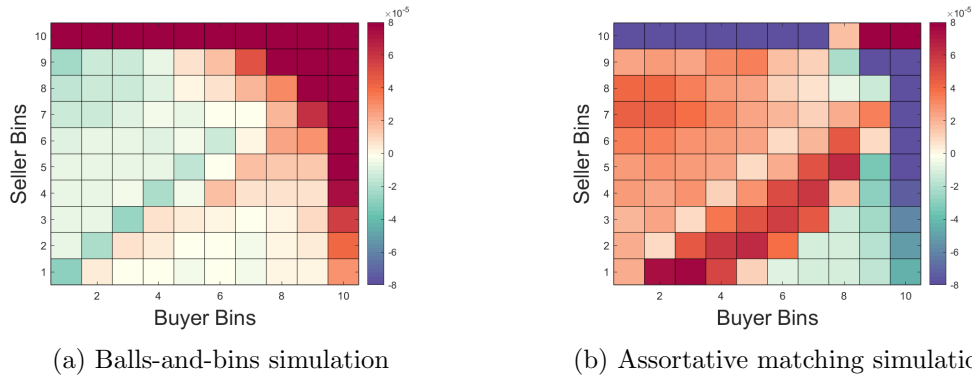

Figure 4: Matching probability: assortative matching simulation

links following the matching mechanism: we take the total number of connections of each buyer and seller as given from the data. Starting from the largest buyer, we assign its largest connection (in terms of total sales) to the most-connected seller, its second-largest connection to the second-most-connected seller, and so forth. After completing assigning the links of the largest buyer, we move to the second-largest buyer and repeat the process. In every round, we assign the buyer to the most connected seller that still has slots.²⁶

The matching probability generated from Beckerian matching is presented in Figure 4. It captures the fact that large sellers have a higher probability of matching with larger buyers. However, it predicts that for small sellers (buyers), their matching probability decreases in buyer (seller) size (4-a, b), in contrast to the data. Comparing the prediction errors of the matching probability of the elementary model vs. the Beckerian model (Figure 5), we find that the latter has a much higher prediction error for most of the buyer-seller bins. Through the lens of Bayes, this suggests that the data lends less credibility to the Beckerian model in explaining firm-to-firm connections compared to the elementary model. In other words, if we conclude that the Beckerian model is our preferred theory, the justification must come from a strong prior we attached to it.

At first look, this may appear perplexing, as the Beckerian matching model is intended to explain matching, whereas the elementary model does not. However, despite the fact

²⁶In Sugita et al. (forthcoming), matching occurs between the final producer and the supplier. A final manufacturer produces multiple varieties and a supplier has multiple production lines. A variety can be matched with only one production line and vice versa. The matching (in their preferred case C) is characterized by positive assortativity, i.e. more capable producers match with more capable suppliers. The production technology is Leontief, so in equilibrium, more productive matches translate into higher final sales, and more trade between buyers and sellers. Given this, we feel the allocation described above best matches their model. We recognize that there may be different interpretations and designs that do not change the central message of the exercise.

Notes: This figure presents the difference of the predicted matching probability of the elementary model (panel a) and the Beckerian matching model (panel b) with the actual matching probability from the Norwegian trade data in each of the 10 × 10 buyer-seller bins, i.e. $\hat{\rho}_{ij} - \rho_{ij}$. If the value is greater (less) than 0 it implies the model over-predicts (under-predicts) the matching probability for the given buyer-seller group.

Figure 5: Prediction errors of matching probability

that the Beckerian matching model was designed to explain firm-firm linkages, whose data counterpart is ρ_{ij} , in practice it only matches only *certain statistics* of ρ_{ij} , such as the sign of assortativity. To match these statistics, strong assumptions are imposed, which in turn generate greater prediction errors in matching the *distribution* of ρ_{ij} . Without comparing a model to alternatives, we may make incorrect conclusions about its plausibility, leading to mistaken conclusions on mechanisms, causal interpretations, and welfare or policy predictions.

7.2.2 Network Models: A Quantitative Comparison

In this subsection, we apply the idea of model selection to compare several candidate network models quantitatively. From the Bayesian view, discovering that the data has a high or low probability given a theory says nothing about the probability of the theory itself unless we can compare it to an alternative. Therefore, the choice of an appropriate alternative model is paramount. The elementary model is an appealing candidate because of its simplicity and because it can easily be extended and mapped into existing economic models. In this section, we further show that the elementary model is also so far the best alternative from a data perspective, and thus a reasonable benchmark model for work on production networks.

We consider three class of network models besides the elementary model: (1) the Erdős–Rényi model (ER), where every pair of buyer-sellers is independently linked with probability ρ ; (2) the Fixed-degree Random Graph model (FRG), where links are randomly

Table 2: Production Network Model Selection

Erdős-Rényi	Fixed-degree	Elementary Model			Beckerian	
	Random Graph	Baseline	$\hat{b} = \hat{b} + \hat{}$	Trans. uncertainty	Baseline	Optimal Error
(1)	(2)	(3)	(4)	(5)	(6)	(7)
-9.99 $\hat{p} = 1.25e^{-4}$	-17.82	-8.22	-7.73 $\hat{} = 0.57$ $\hat{} = 0.33$	[-9.00, -8.18] $\hat{} = 0.21; 1.51$ $\hat{} = 1.45; 1.35e^{-05}$	-73.47	-18.58 $\hat{} = 2.48e^{-4}$

Notes: The maximized log-likelihood (per link) is presented in bold in the first row for each given model. The remaining rows are the parameter values that maximize the log-likelihood of a given model conditional on the observed Norwegian network.

allocated conditional on taking each buyer and seller’ degree as given;²⁷ (3) the Beckerian model. The first two models have been widely used in the broader network literature either as the foundation of more elaborate network models or as a baseline for falsification. Of course one can propose more complicated models, but our focus is on selecting a benchmark.

Each of the aforementioned models can be specified by a set of parameters.²⁸ For a fixed set of parameters, the model induces a probability distribution of the production network. If we hold a uniform prior, i.e., before the arrival of the data, we believe each model is equally probable, then selecting the best posterior model is equivalent to ask which model gives the largest likelihood to the observed data. In the interest of space, we discuss each model and its associated likelihood function in Appendix B.3.

The estimated results are presented in Table 2. The first row of shows the maximized log-likelihood of a given model, which we normalize by the total number of links observed in the data. Its value reflects the likelihood of observing the sample network if the associated model is the true model. The rest of the rows report any estimated parameter values. The elementary model yields the highest likelihood value, the baseline case (column 3) is about 6 times as large as the likelihood value of the Erdős–Rényi model (column 1). When we allow

²⁷For example, the Power-law Random Graph model proposed by Aiello et al. (2001) is one special case of the Fixed-degree Random Graph model, in which the degree distribution of firms (nodes in the network) is drawn from a Power-law distribution.

²⁸When there are parameter uncertainties and under a uniform prior, the posterior probability $P(M | D)$ is proportional to $P(D | M; \hat{M}_L)P(\hat{M}_L | M)$, where \hat{M}_L is the vector of parameters that maximize the likelihood given the model class M . The Bayesian evidence $P(D | M)$ is dependent not only on the best-fit likelihood but also on our prior beliefs about how likely \hat{M}_L is given the model class M . Typically, a model with many free parameters is penalized by having a smaller $P(\hat{M}_L | M)$ than a simpler model. In other words, Bayesian inference naturally embodies Occam’s Razor. We avoid a more detailed discussion in the main text for two reasons: first, $P(\hat{M}_L | M)$ only depends on priors, and second, the candidate models have no more than two free parameters, making over-fitting less of an issue. Furthermore, the preferred model has no free parameters at the end. Nevertheless whenever we report and discuss $P(D | M; \hat{M}_L)$, we bear in mind its differences from $P(D | M)$.

for optimal prediction errors in column (4), the likelihood value of the elementary model only improves marginally, suggesting that the baseline is a reasonable good description of the data. Column (5) shows that even when transaction-level data are unobservable, the elementary model with a simple assumption on ball size still gives a better fit than the other models. Somewhat surprisingly, Erdős–Rényi model ranks the second in fitting data despite its simple structure. FRG model ranked third, followed by the Beckerian model. The fact that the elementary model outperforms the Erdős–Rényi model and the FRG model emphasizes the importance of the stochastic nature of production networks. As expected, the naive prediction of the Beckerian model fits the data poorly, as shown in column (6) of Table 2. While introducing prediction errors in column (7) greatly improves the model fit, it still has the least explanatory power among all the models. Overall, based on the log-likelihood values presented in Table 2, the elementary model is the logical choice as a baseline model for future comparisons.

8 Conclusion

Firm heterogeneity and the sparse nature of the production network implicitly discipline the structure of the network, even when links are formed randomly. In this case, a large group of statistical relationships, in both levels and changes, may not be informative in improving our understanding of production networks beyond random matching.

We provide a benchmark elementary model to distinguish which statistics are sufficiently characterized by random matching and which require additional model assumptions. In addition to revisiting the set of stylized facts and empirical results commonly presented in the trade literature, we develop the general properties of the model, characterizing families of statistics and data generating processes that may cause a model to suffer from underidentification concerns. We propose ways to use the elementary model to discern useful statistics and select applied models. We also provide an economic interpretation of the model by showing that it naturally emerges from a competitive environment. This view not only disciplines falsification designs but also helps select appropriate data counterparts given the economic context of a study. These results can be helpful for various research fields, in particular for future applied work on firms using large micro-level data sets.

The results of this paper point to several interesting directions for future research. The

fact that the elementary model provides a good fit to buyer-seller matches suggests that it may be possible to reasonably identify production network structure without the network data. Related, the elementary model may also be useful in partialing out the non-random network exposure and correcting for omitted variable bias in empirical estimations. From a structure perspective, how to do testing and inference properly for model comparison, and how to compute counterfactuals taking into account data granularity and modeling uncertainty can be important areas for future research. Finally, although the focus here is on production networks, we believe the findings of this paper can be useful for other areas, as bipartite relationships are at the foundation of many economic problems and the prior-selection problem potentially exists whenever theory is linked to data.

Appendix A Theory Appendix

A.1 Coupling and Stochastic Dominance Theorem

Because this is the first time that the coupling technique has been employed in the network and trade literature, we provide a pedagogical introduction of the method and its relation with the stochastic dominance theorem with examples for interested readers.

Coupling is an essential probabilistic technique with a wide range of applications in statistics. The idea behind the coupling method is that to compare two random variables X and Y , it is sometimes useful to construct their joint probabilities. Formally, let X and Y take values in $(S; S)$, where S is a measurable space. A coupling of X and Y is a probability measure $Z := (X^\theta; Y^\theta)$ on the product space $(S \times S; S \times S)$, such that the marginal distributions of Z equal to the distributions of X and Y .

There are multiple ways to couple random variables. Consider two Bernoulli random variables X_1 and Y_1 as an example. Let $P[X_1 = 1] = q$ and $P[Y_1 = 1] = p$, and p is greater than q . Here, $S = \{0, 1\}$. The followings, for example, are two couplings of X_1 and Y_1 :

- (Independent coupling) One obvious way of construct coupling is to let X_1^θ and Y_1^θ be independent. In this case, the joint distribution is given by:

$$P[(X_1^\theta; Y_1^\theta) = (i; j)]_{i, j \in \{0, 1\}} = \begin{pmatrix} (1-q)(1-p) & (1-q)p \\ q(1-p) & qp \end{pmatrix}$$

- (Monotone coupling) Another possibility is to set $X_1^{\theta\theta} = X_1$, and $Y_1^{\theta\theta} = 1$ whenever $X_1^{\theta\theta} = 1$. When $X_1^{\theta\theta} = 0$, set a probability $(1-p)/(1-q)$ that $Y_1^{\theta\theta} = 0$ and a probability $(p-q)/(1-q)$ that $Y_1^{\theta\theta} = 1$. In this case, the joint distribution is given by:

$$P[(X_1^{\theta\theta}; Y_1^{\theta\theta}) = (i; j)]_{i, j \in \{0, 1\}} = \begin{pmatrix} 1-p & p & q \\ 0 & q & 0 \end{pmatrix}$$

It is easy to verify that in both cases, the marginal distributions of the couplings equal the distributions of X_1 and Y_1 . Moreover, in the second case, $X_1^{\theta\theta}$ being greater than $Y_1^{\theta\theta}$ is a sure event.

Armed with the definition of coupling, we next briefly discuss its relationship with the stochastic dominance theorem. When ordering random variables, two sets of information are important for the ordering: (1) the values that the random variables can take and (2) the associated probability. If two random variables X and Y , we say that either X has a higher probability of obtaining larger values than Y , or X has a tendency to be greater than Y . The first view corresponds to the definition of first-order stochastic dominance. That is, conditional on values, we compare the two random variables' associated probability. Coupling takes another approach and corresponds to the second view: conditional on probability and comparing the values. This intuition is best seen from the construction of the following coupling: if two random variables X and Y with the cumulative distribution function (cdf) are F_X and F_Y , let $(X^\theta; Y^\theta) = (F_X^{-1}(U); F_Y^{-1}(U))$, where U is uniform in $[0; 1]$. By construction, $(X^\theta; Y^\theta)$ is a coupling of X and Y . Given this coupling, we transferred the problem from comparing the probability that X and Y take less than or equal to a certain value, to comparing the value of $F_X^{-1}(U)$ and $F_Y^{-1}(U)$ for a certain probability event (e.g., the probability of U equal to or smaller than a certain value). This is precisely the intuition behind stochastic dominance theorem.

In other words, when we use the notion of first order stochastic dominance to compare two random variables, we are anchoring *values* and comparing *probabilities*. The stochastic dominance theorem, on the other hand, allows us to translate the problem to anchoring *probabilities* and comparing *values*. Economic models usually apply functional transformations on the value side, hence when using the stochastic dominance theorem, we do not need to alter the anchoring every time when making comparisons. As a result, we can perform comparative statics for probabilistic models in the same way that we do for deterministic models.

A.2 Degree Assortativity

The in-degree of a buyer is the number of sellers the buyer matches. Its expected value is given by equation (3) and increases in b_j . We only need to prove that the average number of connections of sellers that a buyer matches,

$$\bar{N}^s(j) = \frac{\sum_i N_i^s p_{ij}}{\sum_i p_{ij}} := \sum_i N_i^s g(i; j);$$

decreases in b_j . Here N_j^S is an increasing function of i and $g(i; j) = \frac{p_{ij}}{\sum_i p_{ij}}$ gives the relative probability of i matching j . Note that $\sum_i g(i; j) = 1$. By the ranking theorem, if we can prove that $g(i; j^\theta) \geq g(i; j)$ for any two buyers $j > j^\theta$, then $\bar{N}^S(j^\theta) > \bar{N}^S(j)$ is immediate.

According to the elementary model,

$$\begin{aligned} \frac{\partial^2 \ln p_{ij}}{\partial s_i \partial b_j} &= \frac{\partial^2 \ln(1 - (1 - s_i)^{b_j})}{\partial s_i \partial b_j} \\ &= \frac{\partial \left(\frac{b_j (1 - s_i)^{b_j - 1}}{1 - (1 - s_i)^{b_j}} \right)}{\partial b_j} \\ &= \frac{(1 - s_i)^{b_j - 1} ((1 - s_i)^{b_j} - b_j \ln(1 - s_i) - 1)}{(1 - (1 - s_i)^{b_j})^2} \\ &< 1 - (1 - s_i)^{b_j} + \ln(1 - s_i)^{b_j} < 0: \end{aligned}$$

Because $(1 - s_i)^{b_j}$ take values ranging from zero to one, $1 - (1 - s_i)^{b_j} + \ln(1 - s_i)^{b_j}$ is always negative. Therefore,

$$\frac{p_{ij^\theta}}{p_{i^\theta j^\theta}} > \frac{p_{ij}}{p_{i^\theta j}};$$

for any two buyers $j > j^\theta$. This is equivalent to

$$\frac{g(i; j^\theta)}{g(i; j)} > \frac{g(i^\theta; j^\theta)}{g(i^\theta; j)}.$$

The last of these inequalities coincides with the definition of the monotonic likelihood ratio (*MLR*) property. Therefore, $g(i; j^\theta) \geq_{MLR} g(i; j)$ for every $j^\theta < j$. As *MLR* is a stronger ordering concept and it implies *FSD* (Eeckhoudt and Gollier, 1995), it is immediate that $g(i; j)$ is negatively *FSD* ordered in j . We then establish that $\bar{N}^S(j)$ is negatively associated with b_j . \square

A.3 Robustness: Correlated Assignments

We consider the case in which assignments are not i.i.d events. Without loss of generality, let one purchase be randomly allocated at a time. Assume that at time one, the probability of a seller i receiving a purchase from any buyer is still s_i . At time $1 + \epsilon$, for any $\epsilon > 0$, its

probability of receiving a purchase from buyer j is given by:

$$s_{ij; +1} = \frac{\Omega(s_{ij; } ; 1(x_{ij; } > 0))}{\sum_{i^{\theta}} \Omega(s_{i^{\theta}j; } ; 1(x_{i^{\theta}j; } > 0))}; \quad (\text{A1})$$

where Ω is an increasing function of both s and $1(x > 0)$. That is, the probability that a purchase is assigned to i at time $1 +$ is positively associated with the seller's general attractiveness to j and their realized matching outcome in the previous period. The denominator reflects the fact that the unconditional probability needs to be normalized across all sellers.

Clearly, $s_{ij; +1}$ is a random variable. Naturally, we investigate its stochastic ordering across all buyers and time periods. We first state the results: $s_{ij; }$ is *FSD* statistically ordered in ascending order in i , across all buyers j and periods $t \geq 0$.

We prove the above statement using mathematical induction. Without loss of generality, consider two sellers with $s_i > s_{i^{\theta}}$. When $t = 1$, the statement is trivially true. Suppose that when $t = z$ and $s_{ij; } \geq s_{i^{\theta}j; }$. Then, by the proof of proposition 1, $x_{ij; } \geq x_{i^{\theta}j; }$, which in turn implies $1(x_{ij; } > 0) \geq 1(x_{i^{\theta}j; } > 0)$. View $(s_{ij; } ; 1(x_{i^{\theta}j; } > 0))$ as the input vector; applying proposition 1, it is immediate that $s_{ij; +1} \geq s_{i^{\theta}j; +1}$. Since both the base case and the inductive step have been shown, by mathematical induction, the statement $s_{ij; } \geq s_{i^{\theta}j; }$ holds for every natural number t . \square

Given the above result, the normalized matching probability between i and j over any *period* also follows the *FSD* ordering. Note that whether s_i is deterministic or *FSD* ordered in i does not affect the stochastic ordering of x_{ij} . Therefore, all results derived in the paper remain unchanged when we allow for correlated assignment. Given the proof, it is also clear that the statement also holds for richer dynamics than shown in equation (A1), as long as Ω and the stochastic ordering of the input vector are monotone.

The elementary model explains why the persistence of production links increases with firm size (Huneus, 2019): In an extreme case where a buyer/seller is large enough, she almost certainly matches every seller/buyer; thus, the share of survived links equals one, while the share of newly created links equals zero. Further allowing for path dependence allocations enables the model to explain why a very small number of firms in the data have a large number of connections (Lim, 2020), and why the amount traded within a relationship increases as the firm ages, as does the probability of the relationship surviving (Monarch

and Schmidt-Eisenlohr, 2020).

A.4 Robustness: Unequal-sized Purchases

Two purchases of unequal size can be viewed as two purchases with the same price but different quantities (bundled purchase) or two purchases with the same quantity but different prices. But as long as we are interested in sales-related statistics, this distinction is not important: we loosely refer to the value of a purchase as purchase size. Without the loss of generality, we choose the former view for our proofs.

We first consider the case in which the size of each purchase differs across buyers. Denote by q_j the purchases size for buyer j . All extensive-margin results remain unchanged, but the total sales from i to j now becomes $x_{ij}q_j$. When q_j is weakly increasing b_j , or *FSD* generated in ascending order in b_j , we will have $x_{ij}q_j \geq x_{ij^0}q_{j^0}$ for $b_j > b_{j^0}$. In words, if bigger buyers are more likely to make more purchases when matching a seller, all results derived in the paper remain unchanged.

Proof: When q_j is weakly increasing b_j , then $q_j \geq q_{j^0}$ for $b_j > b_{j^0}$. By the proof of proposition 1, $(\hat{x}_{ij}, \hat{x}_{ij^0})$ is the monotone coupling of x_{ij} and x_{ij^0} , $P(\hat{x}_{ij} > \hat{x}_{ij^0}) = 1$. Therefore, $P(\hat{x}_{ij}q_j > \hat{x}_{ij^0}q_{j^0}) = 1 \Rightarrow x_{ij}q_j \geq x_{ij^0}q_{j^0}$.

When q_j is *FSD* generated in ascending order in b_j , then $q_j \geq q_{j^0}$ for $b_j > b_{j^0}$. By the stochastic dominance theorem, monotone coupling also exists for q_j and q_{j^0} , which we denote by $(\hat{q}_j, \hat{q}_{j^0})$. Then, $(\hat{x}_{ij}\hat{q}_j, \hat{x}_{ij^0}\hat{q}_{j^0})$ form a coupling of $x_{ij}q_j$ and $x_{ij^0}q_{j^0}$. Clearly, $P(\hat{x}_{ij}\hat{q}_j > \hat{x}_{ij^0}\hat{q}_{j^0}) = 1$; therefore, $x_{ij}q_j \geq x_{ij^0}q_{j^0}$. \square

Similar proofs can be constructed for the following two cases. When the size of each purchase differs across sellers, denote by q_i the purchases size from seller i . The extensive-margin results remain unchanged, but the total sales from i to j now becomes $x_{ij}q_i$. When q_i is weakly increasing s_i , or *FSD* generated in ascending order in s_i , we will have $x_{ij}q_i \geq x_{ij^0}q_{i^0}$ for $s_i > s_{i^0}$. In words, if buyers are more likely to buy more when matched with a bigger seller, all results derived in the paper also remain valid. Alternatively, consider the case in which the size of each purchase is match specific. Denote it by $q(s; b)$. The total sales from i to j now becomes $x_{ij}q_{ij}$. Again, it is obvious that when q is an increasing function of s and b or is *FSD* generated in ascending order in s_i and q_j , we will continue to have that $x_{ij}q_{ij} \geq x_{ij^0}q_{i^0j^0}$ for $b_i > b_{i^0}$ and $s_i > s_{i^0}$.

Adding purchase-size heterogeneity to the model is equivalent to adding one more pa-

parameter; thus, purchase-size can be considered another variable of interest. The results of Section 4.4 apply directly.

A.5 Robustness: Conditional on Realizations

In practice, empirical regularities are calculated based on the statistics of realized assignment rather than the fundamental parameters s or b . When examining the relationship between total sales and out-degree, for example, we group sellers with the same realized number of connections, compute their average sales and compare it with the same statistic computed for a different group of sellers with a higher number of realized connections.

Formally, consider two statistics, \hat{t} and \tilde{t} . Without loss of generality we consider seller statistics, such that both \hat{t}_i and \tilde{t}_i are statistics of realized assignment result and can be *FSD* ranked in ascending order of i . Under what conditions can \hat{t} be *FSD* ranked in ascending order of \tilde{t} ? One sufficient condition is that \tilde{t} on the x-axis follows the monotonic probability ordering (*MPR*) in i .

The proof is the following. Let $u(\hat{t})$ be an increasing and piecewise differentiable function. Then, $E(u(\hat{t}) \mid \tilde{t})$ is given by

$$\begin{aligned} E(u(\hat{t}) \mid \tilde{t}) &:= \sum_{\hat{t}} u(\hat{t}) P[\hat{t} \mid \tilde{t}] = E_i(E(u(\hat{t}) \mid \tilde{t}; i)) \\ &= \sum_i E(u_i(\hat{t}) \mid \tilde{t}) P[i \mid \tilde{t}], \end{aligned}$$

where the second equality is ensured by the law of iterated expectations. The variable $P[i \mid \tilde{t}] = \frac{P[\tilde{t}_i = \tilde{t}]}{\sum_i P[\tilde{t}_i = \tilde{t}]}$ and is the probability that the realized value \tilde{t} comes from seller i .

Consider two sellers with $s_i > s_{i^0}$. We first prove that $E(u_i(\hat{t}) \mid \tilde{t})$ is an increasing function of i . For our purpose, it is sufficient to consider the case when \hat{t} is a monotone or order statistic. If \hat{t} is a monotone statistic, based on the proof of proposition 1, we know that we can always construct coupling $(u_i^\beta(\hat{t}); u_{i^0}^\beta(\hat{t}))$ with $P[u_i^\beta(\hat{t}) > u_{i^0}^\beta(\hat{t})] = 1$ for $u_i(\hat{t})$ and $u_{i^0}(\hat{t})$. If \hat{t} is an order statistic, we proved its stochastic dominance in the proof of proposition 4. Hence by the stochastic dominance theorem we know the monotone coupling of \hat{t}_i and \hat{t}_{i^0} also exist, hence so does that of $u(\hat{t}_i)$ and $u(\hat{t}_{i^0})$. Then, by the monotonicity of conditional expectation, we have that $E(u_i(\hat{t}) \mid \tilde{t}) > E(u_{i^0}(\hat{t}) \mid \tilde{t})$.

Now we proceed with the second step of the proof: if $\tilde{t}_i \text{ }_{MPR} \tilde{t}_{i^0}$, then for any two

values $\tilde{t}^0 > \tilde{t}^{00}$. Note that if $\tilde{t}_i \succ_{MPR} \tilde{t}_{j^0}$, we have

$$\frac{P[\tilde{t}_i \succ \tilde{t}^0]}{P[\tilde{t}_{j^0} \succ \tilde{t}^0]} > \frac{P[\tilde{t}_i \succ \tilde{t}^{00}]}{P[\tilde{t}_{j^0} \succ \tilde{t}^{00}]} \implies \frac{P[\tilde{t}_i \succ \tilde{t}^0]}{P[\tilde{t}_i \succ \tilde{t}^{00}]} > \frac{P[\tilde{t}_{j^0} \succ \tilde{t}^0]}{P[\tilde{t}_{j^0} \succ \tilde{t}^{00}]},$$

where the first inequality directly comes from the definition of MPR . The second inequality in turn implies that $P[i \succ j \mid \tilde{t}]$ has the MPR property. Therefore, by the well-known result that $MLR \implies MPR \implies FSD$ (e.g., Eeckhoudt and Gollier, 1995), the distribution $P[i \succ j \mid \tilde{t}^0]$ FSD the distribution $P[i \succ j \mid \tilde{t}^{00}]$. Using the ranking theorem, we then have

$$E[u(\hat{t}) \mid j \succ i = \tilde{t}^0] > E[u(\hat{t}) \mid j \succ i = \tilde{t}^{00}];$$

which holds and any increasing and piecewise differentiable function $u(\hat{t})$. Therefore, applying (the reverse of) the ranking theorem, we complete the proof that that \hat{t}_i can be FSD ranked in ascending order of \tilde{t} .

In the elementary model, the distribution of seller sales is binomial. The distribution of the number of buyers a seller matches with is Poisson binomial and is asymptotically Poisson when N is large and s is small. The total purchases of buyers are deterministic; the number of sellers that a buyer matches with is asymptotically normal (Holst, 1972; Weiss, 1958). To the best of our knowledge, these four statistics cover all x-axis variables researchers have used do date. In all cases, the distributions satisfy MPR stochastic orderings.²⁹

A.6 Additional Proofs for Section 6.2

Intensive margin adjustment (the formal proof of $\frac{\partial^2 E(\log(x_{ij}))}{\partial b_j \partial s_i} < 0$)

Note that the partial derivative of a binomial distribution $Bin(b; s)$ is given by:

$$\frac{dP(Bin(b; s) = x)}{dp} = P(Bin(b; s) = x) \left(\frac{x}{s} - \frac{b-x}{1-s} \right);$$

$$\frac{dP(Bin(b; s) = x)}{dn} = P(Bin(b; s) = x) (\log(1-s));$$

²⁹Poisson and normal distributions have the MLR property, which is sufficient to guarantee MPR ordering. The proof of the stochastic ordering of the discrete distributions can be found in, for example, Klenke and Mattner (2010).

Hence,

$$\begin{aligned} \frac{\partial^2 P(\text{Bin}(b; s) = x)}{\partial b \partial s} &= P(\text{Bin}(b; s) = x) \left(\frac{x}{s} - \frac{b-x}{1-s} \right) \log(1-s) - P(\text{Bin}(b; s) = x) \frac{1}{1-s} \\ &= P(\text{Bin}(b; s) = x) \left(\left(\frac{x}{s} - \frac{b-x}{1-s} \right) \log(1-s) - \frac{1}{1-s} \right); \end{aligned}$$

the first term on the RHS, $P(\text{Bin}(b; s) = x)$, is always positive. The second term, $\left(\frac{x}{s} - \frac{b-x}{1-s} \right) \log(1-s) - \frac{1}{1-s}$, is increasing in x and approaches 0 when $x \rightarrow 1$. Therefore, the whole term is negative, therefore we proved that $\frac{\partial^2 P(\text{Bin}(b; s) = x)}{\partial b \partial s} < 0$.

Then we can directly apply this result. Recall that a fall in the exchange rate is equivalent to all buyers at destination market c increasing the number of purchases from b_j to \tilde{b}_j , where $\tilde{b}_j > b_j$. And by proposition 3 we can view all buyers from country c as one buyer with $b_c = \sum_{j \in 2c} b_j$. Therefore, ρ_c have the same sign as

$$\begin{aligned} &\sum_x \ln(x) (P(\text{Bin}(b_c; s_i) = x) - P(\text{Bin}(b_c; s_{i^0}) = x)) \\ &\sum_x \ln(x) (P(\text{Bin}(b_c; s_i) = x) - P(\text{Bin}(b_c; s_{i^0}) = x)) < 0; \end{aligned}$$

where $s_i > s_{i^0}$. Therefore $\rho_c < 0$. \square

Extensive margin adjustment

The probability that a seller matches which each buyer is an independent event with probability ρ_{ij} . The number of buyers that a seller matches with follows a Poisson binomial distribution:

$$P(n_i^S = \ell) = \sum_{A \subseteq B} \prod_{j \in A} \rho_{ij} \prod_{j \in A^c} (1 - \rho_{ij});$$

where B is the set of all subsets of \mathcal{M} integers that can be selected from $\{1, 2, \dots, M\}$. The set A^c is the complement set of A . Therefore

$$\begin{aligned} P^{post}(n_i^S = \ell) - P^{post}(n_{i^0}^S = \ell) &= P(n_i^S = \ell) - P(n_{i^0}^S = \ell) = \sum_{A \subseteq B} \prod_{j \in A} \rho_{ij}^{post} \prod_{j \in A^c} (1 - \rho_{ij}^{post}) \\ &\quad - \prod_{j \in A} \rho_{ij} \prod_{j \in A^c} (1 - \rho_{ij}) - \prod_{j \in A} \rho_{i^0 j}^{post} \prod_{j \in A^c} (1 - \rho_{i^0 j}^{post}) + \prod_{j \in A} \rho_{i^0 j} \prod_{j \in A^c} (1 - \rho_{i^0 j}); \end{aligned}$$

where $S_i > S_i^0$, and the superscript *post* denote the post-shock variables. In this case, the latter refers the increase in the number of purchases from b_j to b_j^0 for all buyers in market c . As B remains unchanged, to prove $\frac{\partial^2 P(n_i^s)}{\partial S_i \partial b_j} < 0$, it is sufficient to show that

$$\begin{aligned} & \prod_{j \in A} p_{ij}^{post} \prod_{j \in A^c} (1 - p_{ij}^{post}) - \prod_{j \in A} p_{ij} \prod_{j \in A^c} (1 - p_{ij}^0) \\ & \prod_{j \in A} p_{ij}^{post} \prod_{j \in A^c} (1 - p_{ij}^{post}) + \prod_{j \in A} p_{ij} \prod_{j \in A^c} (1 - p_{ij}^0) < 0 \end{aligned} \quad (A2)$$

for all $A \supseteq B_k$. Note that

$$\begin{aligned} & \frac{\partial \left(\frac{p_{ij}^{post}}{p_{ij}} \right)}{\partial S_i} / \frac{\partial p_{ij}^{post}}{\partial S_i} - \frac{\partial p_{ij}}{\partial S_i} \\ & = b_j (1 - S_i)^{b_j - 1} - b_j (1 - S_i)^{b_j - 1} < 0; \end{aligned}$$

and

$$\begin{aligned} & \frac{\partial \left(\frac{1 - p_{ij}^{post}}{1 - p_{ij}} \right)}{\partial S_i} / \frac{\partial p_{ij}}{\partial S_i} - \frac{\partial p_{ij}^{post}}{\partial S_i} + \frac{\partial p_{ij}^{post}}{\partial S_i} p_{ij} - \frac{\partial p_{ij}}{\partial S_i} p_{ij}^{post} \\ & = b_j (1 - S_i)^{b_j + b_j - 2} - b_j (1 - S_i)^{b_j + b_j - 2} < 0; \end{aligned}$$

Therefore, $\frac{\prod_{j \in A} p_{ij}^{post} \prod_{j \in A^c} (1 - p_{ij}^{post})}{\prod_{j \in A} p_{ij} \prod_{j \in A^c} (1 - p_{ij}^0)}$ decreases in S_i , which guarantees the equality in (A2).

The remainder of the proof is simply identical to the proof of $\frac{\partial^2 E(\log(x_{ij}))}{\partial b_j \partial S_i} < 0$. \square

Appendix B Empirical Appendix

B.1 The Norwegian trade data

The Norwegian trade data used in the paper is transaction-level customs data, which has information on the identity of the seller and buyer of each trade transaction involving a Norwegian firm. Without loss of generality, we use the data from year 2005 and focus on Norwegian exporters and their international buyers (unless otherwise mentioned). The data include all Norway’s non-oil commodity exports, which account for 18% of the Norwegian GDP of the corresponding industry. The firm and transaction-level variables and characteristics of this dataset are similar to those of other countries and other databases, as detailed in Bernard et al. (2018a).

The firm-to-firm transaction-level data is the most disaggregated data available and is the basis for calculating more aggregate statistics such as annual firm sales to individual buyers or country level trade volumes. A striking feature of the transaction-level data is its discreteness. For buyers and sellers with positive transactions, the mean number of transactions is 2.1, and the median is 1. More than 68% of connected buyers and sellers traded only once, and more than 90% of connected buyers and sellers trade fewer than five times in a year.

B.2 US Manufacturing Exporter Share

Table A1: Share of Manufacturing Exporters in the US: US Firms as Bins Simulations

<i>Bins are</i>	<i>US Customs Reporting Cutoff</i>					
	2000 USD (DATA)			36000 USD (AK)		
	Firms	Countries	RoW as one bin	Firms	Countries	RoW as one bin
	(1)	(2)	(3)	(4)	(5)	(6)
<i>Ball Size = 100USD</i>	11.18 %	79.49 %	90.87 %	0.43 %	38.88 %	60.18 %
<i>Ball Size = Cutoff Size</i>	92.66 %	92.63 %	92.63 %	66.53 %	66.61 %	66.61 %

Notes: Each number in this table is the share of direct exporters among US manufacturing firms calculated from a separate balls and bins simulation of a random allocation model. The simulation has buyers (firms, countries, or ROW/US), throwing balls and US manufacturing firms as bins. Simulations vary in ball (transaction) size, the import reporting cutoff, or the aggregation level of the buyer.

Table A1 shows the predicted share of direct exporters in US manufacturing firms when exporters are bins, and buyers are throwing balls. Three levels of aggregation for buyers are represented: firms (domestic and foreign buyers), countries (US, Canada, China etc), and two buyers, US and non-US. The results are very similar to those reported in Table 1 where selling firms are throwing balls and buyers are given by bins.

B.3 Candidate Models and the Computation

ER model. In the Erdős–Rényi model (ER), every pair of buyer-sellers is independently linked with probability ρ . Recall that M is the number of buyers and N is the number of sellers. Let L be the total number of links observed in the data. Therefore the probability that the ER model generates network G is $L_{ER}(G) = \rho^L(1 - \rho)^{MN - L}$. In this model, the optimal probability ρ that maximize $L_{ER}(G)$ can be solved analytically and is given by $\hat{\rho} = \frac{L}{MN}$. The maximized likelihood is then given by $L_{ER}(G) = \hat{\rho}^L(1 - \hat{\rho})^{MN - L}$.

FRG model. The FRG model takes the total number of links of a firm as given and randomize links between buyers and sellers. Compared to the elementary model, it is the links rather than transactions that are randomized. Recall that the realized number of links of seller is denoted by n_i^s and buyer by n_j^b . As in Bezáková et al. (2006), for a network without multiple edges (i.e., more than one link between a pair), the probability of any particular matching is given by $L_{FRG}(G) = \frac{\prod_i n_i^s! \prod_j n_j^b!}{L!}$. Note that when we interested in the likelihood of the model conditional on the observed firm-degrees, there are no free parameters need to be estimated. The maximized likelihood is then directly given by $L_{FRG}(G)$.

Beckerian model. For the Beckerian model, the predicted matching is generated as in Section 7.2.1: we take the total number of connections of each buyer and seller as given from the data. We start from the largest buyer, assign its largest connection (in terms of total sales) to the most-connected seller, second-largest connection to the second-most-connected seller, and so forth. After completing assigning the links of the largest buyer, we move to the second-largest buyer and repeat the same process. In every round, we assign the buyer to the most connected seller that still has slots and with which the buyer has not yet been connected. By doing this, the model gives predicted probability either equal to 1 or 0. As $\ln(\rho_{ij})$ is undefined when $\rho_{ij} = 0$, we set $\rho_{ij} = 1 - 0.1^{16}$ if the model predicts a match between i and j and $\rho_{ij} = 0.1^{16}$ otherwise. This treatment is equivalent to allowing for

Figure A6: The error structure

small prediction errors (see the later discussion on hierarchy model with optimal errors). The probability that the model generates the observed network structure is then given by $L_{Beckerian}(G) = \prod_i \prod_j p_{ij}^{D_{ij}} (1 - p_{ij})^{1 - D_{ij}}$, where D_{ij} denote the matching outcome between i and j observed in the data.

Beckerian model with prediction errors. Typically, when we conduct quantitative analysis, we always allow for some prediction errors as we do not expect a simple, stylized model to fit the data perfectly. Viewing through the lens of model selection, this practice, however, needs to be interpreted with caution. The error term also has a structure and generates predictions. To illustrate, consider a general model $y = T(x)$. The likelihood of $y = f(T(x); \cdot)$ is not an evaluation of the credibility of the model $T(x)$, but a combination of $T(x)$ and \cdot .³⁰ This is also the idea behind model averaging, i.e., $y = f(T(x); \cdot)$ should be viewed as an averaging of two models, $y = T(x)$ and $y = \cdot$.

Nevertheless, evaluating the likelihood of a hierarchy models with errors is still a valuable task. Firstly, one may believe that $y = f(T(x); \cdot)$ is the “real” description of the data. Correspondingly, it can also be viewed as a candidate model and be evaluated under model selection. Secondly, the estimated results also inform us to which extent the data can be explained by $T(x)$. If the estimated likelihood improves a lot by introducing \cdot and the estimated \cdot is very large, it indicates a limited ability of $T(x)$ in explaining data, even when $T(x)$ gives the highest likelihood among all candidate models.

Following the above discussion, we consider a simple error structure: there is \cdot probability that the Beckerian matching model makes the wrong prediction for a buyer-seller pair. That is, we set $p_{ij} = 1 - \cdot$ if the model predicts a match between i and j and $p_{ij} = \cdot$ oth-

³⁰The often used form $y = T(x) + \cdot$ is a special case of $y = f(T(x); \cdot)$.

erwise. We then optimally choose ρ_{ij} to maximize $L_{Beckerian}(G) = \prod_i \prod_j \rho_{ij}^{D_{ij}} (1 - \rho_{ij})^{1 - D_{ij}}$. We summarize the error structure in Figure A6.

Elementary model. We consider three variations of the elementary model: the baseline case as we presented throughout the paper, an extension with balls being a function of b_j , and the case when transaction data is not observable. We describe their calculation in turn. As before, the probability that a model generates the observed network structure is then given by $L_E(G) = \prod_i \prod_j \rho_{ij}^{D_{ij}} (1 - \rho_{ij})^{1 - D_{ij}}$, where $D_{ij} = 1$ if i and j are matched in the data, zero otherwise. The value ρ_{ij} is the matching probability between i and j given by the model.

In the baseline case, we let $\rho_{ij} = 1 - (1 - s_i)^{b_j}$ and compute $L_E(G)$ directly. In the extension, we let $\rho_{ij} = 1 - (1 - s_i)^{b_j + d}$, and we optimally choose ρ_{ij} and d to maximize $L_E(G)$. We expect d to be smaller than one, since we showed before that matches in reality tend to be path dependent. In the last case, we set s_i as the export share of firm i . We assume the number of balls, b_j , follows $b_j = d_j + d$. In case (1) we let d equal the total number of connections of the buyer, and in case (2) d equals the buyer's total purchase divided by the minimum order value \$100. Note that when $d = 1$ and $d = 0$, they corresponds to two extreme cases (1) each connection implies one transaction, and (2) each minimum-value order implies one transaction, respectively. We compute s_i and b_j under the associated assumption, then let $\rho_{ij} = 1 - (1 - s_i)^{b_j + d}$ and optimally choose ρ_{ij} and d to maximize $L_E(G)$.
